5 Co-axial electrohydrodynamic atomization was used to prepare core/shell  
6 polymethylsilsesquioxane particles for co-delivery of metformin and glibenclamide in a  
7 sustained release manner. The drug-loaded microparticles were mostly spherical and  
8 uniformly distributed in size, with average diameters between 3 and 5 $\mu$ m across various  
9 batches. FTIR was used to confirm the presence of drugs within the particles while X-ray  
10 diffraction studies revealed drugs encapsulated existed predominantly in the amorphous  
11 state. Intended as systems that potentially can act as depot formulations for long term  
12 release of antidiabetics, a detailed analysis of drug release from these particles was  
13 necessary. Drugs of different solubilities were selected in order to study the effects of  
14 drug solubility from a core/shell particle system. Further analyses to determine how  
15 conditions such as release into a limited volume of media, sampling rate and partitioning  
16 of drug between the core and shell layers influenced drug release were conducted by  
17 comparing experimental and mathematically modelled outcomes. It was found that while  
18 solubility of drug may affect release from such systems, rate of removal of drug (sampling  
19 frequency) which upsets local equilibrium at the particle/solution interface prompting a  
20 rapid release to redress the equilibrium influenced release more.

## 1. Introduction

The International Diabetes Federation estimated about 415 million adults as having diabetes as at 2015 and projected this figure to be 642 million by 2040. About 90% of these are classified under Type2 diabetes, a condition mainly driven by obesity, sedentary lifestyle and increased consumption of unhealthy diets including sugar-sweetened beverages [1, 2]. Oral administration of hypoglycaemic agents, often a biguanide, e.g. metformin, has predominantly been the first line option when medication is required for managing type 2 diabetes mellitus [3, 4]. Defective insulin sensitivity and defective insulin secretion typically coexist in most patients with type 2 diabetes. These two abnormalities contribute to hyperglycaemia [5]. Thus, oral therapy with either biguanides such as metformin that increase sensitivity of peripheral tissues to insulin, or sulfonylureas such as glibenclamide, which stimulate insulin secretion, are sensible approaches to type 2 diabetes mellitus [6]. Considering metformin's utility as an antidiabetic drug as well as some desired physical properties such as aqueous solubility, novel formulations that enable its controlled release for prolonged duration in order to obtain maximum absorption and better bioavailability are highly desirable. For this reason, metformin was selected as a model drug for biguanides. For sulfonylureas, glibenclamide was selected as a model drug due to its poor solubility in water, which in turn causes its limited dissolution and absorption. The low oral bioavailability of the conventional glibenclamide tablets necessitates a formulation approach that could improve upon its poor solubility. These issues have led to large variation in glibenclamide bioavailability between different commercial brands with each brand presenting inter-subject variability.

Sulfonylureas are thought to act by binding to sulfonylurea receptor (SUR)-1 subunits of

1  
2  
3 pancreatic beta potassium channels leading to their closure and subsequent membrane  
4 depolarization which open up voltage-dependent  $\text{Ca}^{2+}$  channels. This ensures a build-up  
5 of intracellular calcium concentrations, consequentially mediating the release of insulin  
6 [7]. Biguanides on the other hand work through complex physiological pathways  
7 mediated by both AMP-activated protein kinase (AMPK)-dependent and AMPK-  
8 independent mechanisms to reduce hepatic glucose production [8].  
9

10  
11 Each of them can be used solely or in combined form when either of them on their own is  
12 not sufficient on bringing down or maintaining blood sugar at safe levels. However, there  
13 remain issues of patient non-adherence which are generally driven by multiple daily  
14 dosing requirements [9, 10]. Considering how effective these active pharmaceutical  
15 ingredients have been in oral formulations for the control of blood sugar levels, the  
16 potential of formulating these as depot preparations for long-term release is an appealing  
17 proposal. Micro and nanoparticle formulations of these hypoglycaemic agents to be  
18 delivered parenterally could offer a more effective control of blood sugar levels as these  
19 drug-loaded particles have a number of advantages including versatility with regards to  
20 delivery for local or systemic effects as well as ease with which they are injected into  
21 tissues or intravenously [11].

44 In this study, electrohydrodynamic (EHD) forming has been utilized in developing core-  
45 shell particle structures [12] where either glibenclamide (model sulfonylurea drug) or  
46 metformin (model biguanide drug) occupies the core while polymethylsilsesquioxane  
47 (PMSQ) polymer makes the shell surrounding the active ingredient [13, 14]. PMSQ was  
48 chosen as it offers chemical durability and being biocompatible, it is a desirable material  
49 for applications in biomedical engineering. In addition to its biocompatibility and  
50 durability, its high hydrophobicity ensures low moisture uptake; a feature that can  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 ultimately be valuable for stability of drugs upon storage. Finally, PMSQ is known to have  
4  
5 physical characteristics that allow them to be processed into hollow spheres [15, 16]. As  
6  
7 this study explored the possibility of formulating core-shell particles which potentially  
8  
9 can be administered parenterally for drug release over extended periods, the features  
10  
11 offered by PMSQ i.e. stability, compatibility, hydrophobicity and processability  
12  
13 underscored the rationale for selecting this polymer for our investigations. With respect  
14  
15 to drugs, the remarkable water solubility differences between metformin and  
16  
17 glibenclamide, in addition to being routinely used oral hypoglycaemic agents, were the  
18  
19 reasons for selecting the two [17]. The disparities in water solubility of the two drugs  
20  
21 made it possible for the influence of solubility on drug release from these particles to be  
22  
23 studied [18, 19]. Various microscopic and spectroscopic techniques were employed in  
24  
25 elucidating the physical characteristics and molecular composition of these structures.  
26  
27 To determine the possibility of metformin and glibenclamide particles functioning as  
28  
29 depot drug releasing systems, a more detailed view of release profiles as influenced by  
30  
31 particle composition, morphology and physical properties was developed. Furthermore,  
32  
33 the likely effects of varying experimental procedures such as frequency of sampling  
34  
35 which hitherto had been considered inconsequential to release outcomes were studied.  
36  
37 Trends observed as well as mathematical modelling of experimental data derived from  
38  
39 release data are discussed, offering further insights into the release of drug from a system  
40  
41 essentially made of uniformly distributed bi-layered spherical particles.

## 52 *2. Materials and Methods*

### 53 *2.1 Materials*

54  
55 Polymethylsilsesquioxane (PMSQ) with an average molecular weight of  $7465 \text{ g mol}^{-1}$  was  
56  
57 provided by Wacker Chemie AG, GmbH (Burghausen, Germany). Metformin  
58  
59  
60

1  
2  
3 hydrochloride with molecular weight of  $165.62 \text{ g mol}^{-1}$  was obtained from Sigma-Aldrich  
4 (Poole, UK). Glibenclamide with molecular weight  $494.61 \text{ g mol}^{-1}$ , used in this work was  
5 purchased from MP Biomedicals (Loughborough, UK). Research grade ethanol (99%  
6 purity) was purchased from Sigma-Aldrich (Poole, UK). All of the above were used as  
7 received.

### 17 *2.2.1 Preparation of the electrospraying solutions containing polymer and active* 18 *ingredients.* 19

20  
21 A 15% (w/v) PMSQ solution was prepared by dissolving an appropriate amount of PMSQ  
22 in ethanol and stirred to ensure complete dissolution. To prepare the metformin particles  
23 (S1), 10 mg of the drug was dissolved in 80 ml of ethanol, and for glibenclamide particles  
24 (S2), 20 mg glibenclamide was dissolved in 80 ml ethanol. For the combined drug  
25 formulation (S3), 10 mg metformin and 20 mg glibenclamide were dissolved in 80 ml  
26 ethanol. Ethanol was used as both drugs as well as PMSQ are freely soluble in it and  
27 rapidly evaporates during electrospraying. Characteristics of the prepared solutions  
28 including electrical conductivity, surface tension and viscosity, measured at ambient  
29 conditions, are shown in Table 1. Electrical conductivity was determined using a  
30 conductivity probe, Jenway 3540 pH/conductivity meter (Cole-Palmer, Stone, UK).  
31 Viscosity was measured using a U-tube viscometer 75 mL Cannon- Fenske Routine  
32 Viscometer (Cannon Instruments, Pennsylvania, USA), while a Kruss tensiometer Model-  
33 K9 (Kruss GmbH, Hamburg, Germany) was used to obtain surface tension values. Distilled  
34 water was used to calibrate the viscometer, tensiometer and electrical conductivity  
35 probe.

Table 1 Properties of solutions used in developing the particles

Solution	Surface Tension (mN/m)	Viscosity (mPa s)	Electrical Conductivity ( $\mu\text{S/m}$ )
Metformin HCL 10mg in 80ml EtOH	$21.2 \pm 0.3$	0.92	$25.4 \pm 0.3$
Glibenclamide 20mg in 80 ml EtOH	$21.4 \pm 0.2$	0.97	$32.3 \pm 0.3$
10mg Metformin HCL + 20mg Glibenclamide in 80ml EtOH	$21.5 \pm 0.2$	0.93	$23.2 \pm 0.4$
PMSQ 15% w/v in EtOH	$21.8 \pm 0.3$	1.36	$0.66 \pm 0.0$

### 2.2.2 Preparation of the drug delivery systems

The prepared solutions were carefully placed into 10 mL airtight syringes to avoid bubble formation during processing, and set to be driven by a pump, Harvard PHD 4400 (Harvard Apparatus, Edenbridge, UK) to deliver precise volume per unit time. A co-axial needle system with inner diameters of 0.6 mm and 1.52 mm and outer diameters of 0.9 mm and 2.03 mm, were connected to a high precision voltage power supply. The positive electrode of a high precision DC voltage power supply HCP 35 65000 (Fug Elektronik, Rosenheim, Germany) was connected to the needle tip. The ground electrode was fixed onto a rectangular metal collector plate. Experiments were carried out under ambient conditions with average room temperature of 21°C and relative humidity of 40-60% throughout the studies. Electrical potential was applied across a fixed working distance of 150 mm between the tip of the co-axial needles tip and the grounded collection platform. The flow rates and the range of applied voltages were tuned in order to establish a stable cone-jet for each system. Different spherical structures incorporating single or two drugs in the core

surrounded by outer polymeric layer were made subsequently. The optimal combinations of flow rates and applied voltage that enabled the processing of various batches of particles are shown in Table 2.

*Table 2 Experimental parameter for each polymeric system*

Polymer System	Inner Flow Rate ( $\mu\text{l}/\text{min}$ )	Outer Flow Rate ( $\mu\text{l}/\text{min}$ )	Applied Voltage (kV)
S1: Metformin-loaded particles	2	8	11
S2: Glibenclamide-loaded particles	6	18	12
S3: Metformin + Glibenclamide-loaded particles	6	18	11

### *2.2.3 Particle morphology and size distribution*

Drug-loaded microparticles were examined by scanning electron microscopy (SEM). The particles were gold sputter-coated with a rotary pump coater Q150R ES (Quorum Technologies, Laughton, UK) for 3 min preceding SEM imaging by Hitachi S-3400n (Hitachi High Technologies, Tokyo, Japan). The size distributions of the particles were obtained from SEM images using Image J software, where the diameter measurements of 300 particles from each batch were taken randomly and the mean diameter was calculated. The size distribution curves were obtained by examining raw measurements using the Image J application (National Institutes of Health, Maryland, USA) and OriginPro software (OriginLab, Northampton, USA). The images and corresponding size distributions are shown in Figure 1.

#### 2.2.4 *X-ray powder diffraction*

The particle structures and loaded active ingredients were studied using D/Max-BR diffractometer (Rigaku, Tokyo, Japan) with Cu K $\alpha$  radiation. Analyses were conducted at 40 mV and 30 mA over 2 $\theta$  range of 5–45° at a rate of 2°/min. Data obtained were converted to diffractograms and evaluated using OriginPro 7.0 software (OriginLab Corporation, Northampton, USA).

#### 2.2.5 *Fourier transform infrared spectroscopy (FTIR)*

In order to establish if the particles produced contained active ingredients as intended, the chemical compositions of the particles were investigated using Attenuated Total Reflection Fourier Transform Infrared spectroscopy (ATR–FTIR) measurements (Bruker Vertex 90 spectrometer), and spectrographs were interpreted using OPUS Viewer version 6.5 software. Each sample had 64 scans at a resolution of 4 cm<sup>-1</sup>. Spectra of the particles were compared to those of the individual drugs and polymers to identify characteristic functional groups in the processed materials. The same parameters were used for background scans before each sample was analysed.

#### 2.2.6 *Focused ion beam (FIB) microscopy*

Cross sectional images of the particles were prepared using ZEISS NV40 FIB/SEM, a cross-beam of focused ion and field emission gun (FEG) electron beam. In the experiments, an ion beam 30 kV, 150-300 pA is used to cut the sphere sample and 1.5 kV was used for imaging the cross section using BSE detector. Particles were gold sputtered for 120 s and mounted on metallic studs.

### 2.2.7 Drug release studies

To measure the amount of drug released from drug-loaded microparticles, a setup in which 40mg of sample was enclosed in a fine metal mesh to ensure total immersion of particles and was placed in a vessel of 40 ml capacity. Body temperature conditions and continuous agitation at 80 rpm were maintained throughout the release study using a benchtop incubated shaker (Sciquip, Newtown, UK). Samples volume of 2 ml were taken at various intervals from the vessel. 2 ml blank media was added after each sampling to maintain a constant volume.

Ultraviolet-visible (UV-Vis) spectroscopy (Jenway 6305 UV/Visible spectrophotometer, Bibby Scientific, Staffordshire, UK) operating at 231 nm was used to quantify amount of metformin sampled during this study. The operating wavelength was obtained after a spectrum scan of 0.003 mg/mL standard metformin solution between 200 and 280 nm. To convert absorbance readings to drug concentrations, a calibration curve and equation were obtained by measuring absorbance of standard metformin solutions in concentrations between 0.0008 and 0.003 mg/mL, from which metformin content in microparticles were derived. The same procedure was undertaken for quantification of glibenclamide at detection wavelength of 300 nm.

## 3 Results and discussions

### 3.1 Particle size and size distribution

SEM images from the three batches were analysed for size and size distribution. The mean particle size (see Figure 1) was lowest for S2 at  $1.66 \pm 0.74 \mu\text{m}$ . This may be attributable to the highest electrical conductivity of the inner solution containing glibenclamide which aids EHD forming. In comparison, for S3, with the same set flow rates, owing to a lower applied voltage and electrical conductivity of the inner solution,

1  
2  
3 the average particle size is higher at  $4.79 \pm 0.48 \mu\text{m}$ . The same reason possibly explains  
4  
5 the differences seen between S1 and S2. When compared, S2 contained an inner solution  
6  
7 with lower electrical conductivity and hence required lower applied electrical potential.  
8  
9  
10 This resulted in a slight increase in the average particle size ( $3.44 \pm 0.44 \mu\text{m}$ )  
11  
12  
13  
14  
15

16 *Figure 1: SEM images and the corresponding size distribution graphs of the developed drug delivery systems S1, S2 and*  
17 *S3. The smooth curve superimposed on each histogram represents a normal distribution with the same mean and*  
18 *standard deviation as the sample.*  
19

20  
21  
22  
23 The differences in the flow rates of S1 compared to that of S2 and S3 were due to  
24  
25 formation of an unstable cone-jet that resulted in wide distribution size and  
26  
27 inconsistency. Therefore the selected values were chosen to ensure a narrow particle size  
28  
29 distribution, which is of immense importance in development of drug delivery system.  
30  
31  
32  
33

### 34 *3.2 Structure and composition*

35  
36 The XRD patterns of the unprocessed PMSQ, metformin and glibenclamide as well as  
37  
38 those of the prepared formulations are shown in Figure 2.  
39  
40  
41  
42  
43  
44  
45

46 *Figure 2: XRD spectrum of a) pure metformin HCL, glibenclamide and PMSQ and b) the developed formulations S1, S2*  
47 *and S3.*  
48  
49  
50  
51

52 The sharp diffraction peaks, representative of pure metformin were notable at  $2\theta$  angles  
53  
54 of  $17^\circ$ ,  $22^\circ$ ,  $23^\circ$ ,  $25.27^\circ$  and  $45^\circ$ . This series of sharp and intense diffraction peaks are  
55  
56 indicative of the crystalline state of pure metformin. The diffraction spectrum of pure  
57  
58 glibenclamide also showed high peak intensities in the region of  $12^\circ$  to  $34^\circ$  of  $2\theta$ ,  
59  
60

1  
2  
3 indicating its crystalline state [20]. PMSQ showed the characteristic broad humps of an  
4  
5 amorphous materials.  
6

7  
8 As observed in the diffractograms acquired for the developed formulation (S1 – S3), the  
9  
10 amorphous nature was most prominent. In all formulations, no characteristic peaks of  
11  
12 metformin and glibenclamide were detected. As revealed in the X-ray diffractograms of  
13  
14 the drug-loaded formulations, the physical states of these particles are predominantly in  
15  
16 amorphous state. The absence of the characteristic sharp peaks seen in the pure drugs  
17  
18 indicate an amorphous solid dispersion of the drugs in the polymer, as well as the  
19  
20 relatively low amounts of drugs present in the core-shell particles.  
21  
22  
23  
24  
25

### 26 *3.3 Particle composition*

27  
28 The molecular compositions of the particles and possible interactions between drug and  
29  
30 polymer during processing were investigated by FTIR. Spectra of the raw materials and  
31  
32 the particles produced are shown in Figure 3. A characteristic band for PMSQ was  
33  
34 observed at  $1130\text{ cm}^{-1}$  [16]. The spectrum of metformin showed characteristic bands at  
35  
36  $3369\text{ cm}^{-1}$  and  $3294\text{ cm}^{-1}$ , pointing to a primary amine (N-H) stretching vibration and a  
37  
38 band at  $3155\text{ cm}^{-1}$  arising from secondary amine stretching. Characteristic bands at  $1622$   
39  
40  $\text{cm}^{-1}$  and  $1567\text{ cm}^{-1}$ , assigned to C-N stretching were also observed. The spectrum  
41  
42 obtained for glibenclamide showed characteristic amide peaks at  $3369\text{ cm}^{-1}$ ,  $3316\text{ cm}^{-1}$   
43  
44 and  $1715\text{ cm}^{-1}$ . The urea carbonyl and N-H stretching vibrations were also observed at  
45  
46  $1615\text{ cm}^{-1}$  and  $1526\text{ cm}^{-1}$ , respectively. The absorption bands between  $2800\text{ cm}^{-1}$  and  
47  
48  $3200\text{ cm}^{-1}$  represent the aliphatic and aromatic C-H bond in this drug. The results  
49  
50 obtained agreed with the published spectrum for the pure drugs [21].  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 *Figure 3: FTIR spectra of pure PMSQ, metformin HCL, glibenclamide and the developed formulations S1, S2 and S3.*  
4  
5  
6  
7  
8

9 The FTIR spectra obtained for the developed formulations predominantly reflected peaks  
10 corresponding to PMSQ. This is to be expected as the formed particles were largely  
11 composed of PMSQ. Nonetheless, peaks at  $1567\text{ cm}^{-1}$ ,  $1622\text{ cm}^{-1}$  and  $1715\text{ cm}^{-1}$  though  
12 significantly diminished to reflect the quantities of drugs entrapped were also present,  
13 implying that indeed the particles contained drugs as intended. The absence of any new  
14 peaks or insignificant shifts in original peaks, when compared to spectra of either drugs  
15 or polymers indicated non-existent intermolecular interactions among the polymers and  
16 drugs.  
17

28  
29

### 30 *3.4 Particle morphology*

31  
32 The morphology of the prepared formulations was studied using FIB/SEM (Fig. 4). The  
33 particles show a well-defined outer shell that encompasses a core, where the majority of  
34 the encapsulated drug is resident. The cross-sectional cuts through the particles are  
35 indicative of a porous core most likely created by spaces left following evaporating  
36 solvents escaping during particle formation. The outermost portion of the particle though  
37 appear to be less porous as the polymer solution from which this layer was formed had  
38 less amount of evaporating solvent, compared to the drug solution that formed the core  
39 (S1, S2 and S3).

### 3.5 Drug release

A major part of this paper is dedicated to the release of antidiabetic drugs of different solubilities from polymeric nanoparticles through a combination of experimental data analysis and mathematical modelling.

#### 3.5.1 Influence of particle size and morphology

The release profile of metformin was studied from formulations S1 and S3 for a duration of 12 hours and 168 hours respectively (Figure 5a).

*Figure 5: Cumulative drug release in the first 5 hours of a) metformin from S1 and S3 formulations b) glibenclamide from S2 and S3 formulations and c) cumulative release of glibenclamide and metformin percentage cumulative release from S3.*

Burst release can be observed for the first 5 hours. This can be explained by diffusion of metformin towards the surface of the polymeric shell as solvent evaporation takes place. The slightly higher dissolution rate of the drug from S3 at 39% can be due to the slightly larger particle size of  $4.79 \pm 0.48 \mu\text{m}$  that allows the incorporation of more unit surface bound drug per surface area.

The burst release of metformin from S1 was 26% within the first 5 hours of drug release. Moreover, the flow rate ratio of metformin solution to PMSQ solution is higher for S3 at weight ratio 1:3 when compared to that of S1 at 1:4, this may explain the slight discrepancies of metformin burst release from the formulation containing both metformin and glibenclamide. A similar set of observations were made for glibenclamide (Figure 5b), the initial burst release was slightly higher from S3 when compared to S2. The EHD flow rates ratio was kept the same for both formulations. Therefore, the slightly

1  
2  
3 higher dissolution rate of glibenclamide from S3 may be explained by more surface bound  
4 drug content in those, considering they are larger than S2. The burst release was also  
5 compared for that of glibenclamide and metformin from S3 to better understand the  
6 effect of aqueous drug solubility. As can be concluded from Figure 5c, metformin  
7 encountered notably higher dissolution rate which may be attributable to higher water  
8 solubility and hence relatively faster diffusion from the polymeric particles to the release  
9 medium. This effect is expected for highly water-soluble drugs. After the first 5 hours of  
10 burst release, metformin and glibenclamide release from the combined S3 formulation  
11 nearly followed the same path (Figure 6a), resembling zeroth order release. Due to the  
12 hydrophobic nature of the PMSQ polymeric carrier, the drug release is mainly driven by  
13 diffusion against the concentration gradient. Thus, movement of drug molecules from the  
14 core, an area with higher drug concentration through channels created within the  
15 particles occurred in order to reach an equilibrium state between the particles and  
16 dissolution media. It is evident from the release profiles, that the frequency of sampling  
17 can also affect the dissolution rate, and this is considered in detail in section 3.5.2 below.

44  
45  
46  
47

48 Higher sampling frequency causes more disturbance to the system and results in further  
49 agitation of the drug delivery systems, which in turn also increases the dissolution rate  
50 as the release medium is continuously refreshed after aliquots are taken. The dissolution  
51 rate increases as there is a shorter time interval in between each sampling. An example  
52 of this can be seen in Figure 6a. For operational reasons samples were taken at 5, 20, 24  
53 and 48 hours, and the effect of the short interval between 20 and 24 hours can be seen as  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 a steep section of the release fraction. The same effect can be seen in Figure 7a and will  
4  
5 be discussed in more detail in section 3.3.5 below.  
6  
7

8 As shown in Figure 6b, the glibenclamide release from S2 follows zeroth order release  
9  
10 after the initial burst release for the first 5 hours, at which point the frequency of sampling  
11  
12 was decreased and samples were withdrawn on hourly basis. The same was done for  
13  
14 metformin HCL release studies from S1 formulation. Although glibenclamide is a poorly  
15  
16 water-soluble drug, the dissolution rate was slightly higher when compared to  
17  
18 metformin, which may be due to smaller average particle size of  $1.66 \pm 0.74 \mu\text{m}$ . This  
19  
20 means that there was a higher surface area to volume ratio which resulted in a higher  
21  
22 dissolution rate of the incorporated drug. This feature of microparticles make them  
23  
24 highly favourable for encapsulation of drugs with low aqueous solubility as the increased  
25  
26 surface area enhance their dissolution. There was little difference between the release of  
27  
28 metformin and glibenclamide suggesting that the hydrophilic nature of the incorporated  
29  
30 drug had little effect on the dissolution rate. The improved dissolution rates, even among  
31  
32 the system with hydrophobic drug agree with previous studies that have reported, that  
33  
34 in general, electrospraying results in formation of microparticles that incorporate the  
35  
36 active ingredient in their amorphous state, resulting in an accelerated drug release [22].  
37  
38 It should be noted that there was higher initial amount of glibenclamide in the prepared  
39  
40 formulations when compared to that of metformin, which to some extent reflects the  
41  
42 initial amounts of drugs incorporated in the particles; 10mg of metformin for S1, 20 mg  
43  
44 of glibenclamide for S2 and for the combined drug formulation (S3), 10 mg metformin  
45  
46 and 20 mg glibenclamide were used.

### 3.5.2 The effect of drug solubility vs sampling rate on drug release

Theoretical modelling of drug release from particles usually assumes the so-called perfect sink conditions – that is, the concentration of the active ingredient in the medium outside the particles is assumed to be negligible. The importance of maintaining appropriate conditions has been noted in the past [23]. It is relatively straightforward to describe this effect. If fluid were to be kept flowing past the particles, so that the particles were always surrounded by fluid containing no active ingredient, then eventually all of the active ingredient could be dissolved. In general, though, release rates are measured in a fixed volume of fluid, so the active ingredient may build up to a significant concentration. Suppose that the solubility of the active ingredient in the particle is much larger than in the surrounding fluid, so that in equilibrium the concentration in the particle  $C_p$  is related to that in the fluid  $C_f$  by  $C_p = K_p C_f$  where  $K_p$  is the partition coefficient. In general, the volume of the particles  $V_p$  will be small compared to the volume of the fluid  $V_f$  so the ratio  $w = V_p/V_f$  will be small. If the system with initial concentrations  $C_{p0}$  in the particles and 0 in the fluid is left until equilibrium is reached with concentrations  $C_{p\infty}$  in the particles and  $C_{f\infty}$  in the fluid, then the released fraction will be  $1/(K_p w + 1)$ . In an experiment though, fluid is sampled and replaced hence the active ingredient concentration in the fluid  $C_f$  is repeatedly reduced, and more material diffuses out of the particle to re-establish the partition equilibrium. It is therefore possible to approach arbitrarily close to complete release, but on a timescale that is determined by the sampling rate. A similar situation holds in a core-shell particle. If spherical symmetry is assumed, with a core of radius  $a$ , outer radius of particle  $b$ , and partition coefficients  $K_1$  between the core and the shell,  $K_2$  between the external fluid and the shell, then if the outer fluid is not replaced during the experiment the final released fraction will be:

$$K_1 / \left( K_1 + K_2 w \sigma^3 + K_1 K_2 w (1 - \sigma^3) \right)$$

where  $\sigma = a/b$ .

In drug release from uniformly dispersed microparticles, where periodic sampling disrupts the established equilibrium by removal of drug from the immediate surrounding of the particles, the frequency of sampling i.e. the rate of drug removal (upsetting the equilibrium) is as important as the solubility of drug in determining how soon complete release of drug occurs. This assumption is confirmed by plots of cumulative drug release versus time (shown in Figures 7a and b) where nearly as much drug was released in a 12-hour study with much frequent sampling (hourly) as in a 7-day study with less sampling frequency. This observation led to further investigation of the influence of sampling frequency on drug release from microparticles.

*Figure 7: a) Cumulative release of metformine and glibenclamide from microparticles containing both drugs over 7 days and b) cumulative release of metformine and glibenclamide from microparticles containing both drugs over initial 12-hour period.*

The two theoretical models used to explain the impact of sampling frequency on drug release from microparticles, one an analytical model and the other a numerical (finite difference) model, are given as supplementary information.

### 3.5.3 Release Rate with Sampling

To exemplify the observations, we show in Figure 8a the release rate based on the finite difference results at a set of sampling times, specifically  $\tau = (0.01, 0.02, 0.03, 0.04, 0.05, 0.1, 0.2, 0.4, 0.6, 0.8, 0.9, 1.1, 1.3, 1.5, 1.7, 1.9, 2.1, 2.3, 2.5)$ . These are selected to form a

1  
2  
3 sequence which is a scaled form of the sampling intervals used in the experiments  
4 reported in Section 3.5.1. The control parameter was  $K_p w = 10$ , and the fraction of fluid  
5 withdrawn for sampling at each point was  $f=0.1$ . The yellow vertical lines on the graph  
6 show the sampling times. One notable feature is that when one shorter sampling interval  
7 is introduced (between  $\tau=0.8$  and  $\tau=0.9$ ) there is a visible kink in the release graph: this  
8 is also observable in the experimental results in Figures 6 and 7.  
9  
10  
11  
12  
13

22 *Figure 8: a) Finite difference predictions of the release fraction obtained with sampling for the case  $K_p w = 10$  and sample*  
23 *fraction  $f=0.1$ . The yellow vertical lines show the sampling times, b) finite difference predictions of the release fraction*  
24 *obtained with sampling for the case  $K_2 w = 10$  and sample fraction  $f=0.1$ . The blue line shows the evolution of the release,*  
25 *following every step  $\Delta\tau$  of the calculation. The red line shows the release profile that would be obtained with constant*  
26 *sampling at a rate  $f=1$ , according to equation 32 (in Supplementary Information), and the orange line shows what would*  
27 *be seen without sampling and c) finite difference predictions of the release fraction obtained with different sampling for*  
28 *the case  $K_p w = 10$  and sample fraction  $f=0.1$*   
29  
30  
31

32 Rather more insight can be gained by plotting the release at every time-step, rather than  
33 just at the sampling times. This is done in the blue line in Figure 8b, where the release  
34 expected predicted for sampling at a steady rate, (equation 32 in Supplementary  
35 Information), is shown in red and the result without sampling, (equation 28 in  
36 Supplementary Information), is shown in orange. Two points are immediately obvious.  
37 First, sampling has had a marked effect on the total release (Figure 8b). Second, within  
38 each sample period it is clear that the reduction in solution concentration upsets the local  
39 equilibrium at the particle/solution interface, prompting a rapid release to redress the  
40 equilibrium, followed by slower release at the rate expected for the current  
41 concentration. If uniformly-spaced samples are taken, the resulting release profiles will  
42 be smooth, but the results will depend on the sampling interval. This is shown in  
43 Figure 8c, where the release fractions are shown for the case  $K_2 w = 1$ ,  $f=0.1$ , but with  
44

58  
59  
60

1  
2  
3 sampling intervals  $\Delta\tau=0.10$  and  $\Delta\tau=0.25$ . We should note that if the sampling interval is  
4  
5 decreased so as to follow the earlier part of the release this will itself affect the release  
6  
7 rate. An important conclusion is that, because the sampling interval can affect the shape  
8  
9 of the release curve, conventional approaches to characterising release mechanisms [24]  
10  
11 cannot be applied under these conditions.  
12  
13  
14  
15  
16

#### 17 *4 Clinical Perspectives*

18  
19  
20 In terms of the clinical context of this work, it has the potential to provide a novel and  
21  
22 much needed solution to many clinical conundrums. Namely; patient drug compliance,  
23  
24 high dosage associated side-effects, poor oral absorption, erratic glycaemic control and  
25  
26 therefore a reduction in the morbidity and mortality of diabetes - a common condition  
27  
28 that has a rising incidence.  
29

30  
31 Diabetes is a global pandemic affecting 422 million worldwide - quadruple the number  
32  
33 since 1980. The cost of diabetes to the NHS is over £1.5m an hour, this equates to over  
34  
35 £25,000 being spent on diabetes every minute and an annual estimated spend of £14  
36  
37 billion, with the cost of treating complications representing a much higher cost. It has  
38  
39 micro and macrovascular complications that can have a devastating impact on patient  
40  
41 quality of life, ranging from impotence to fulminant renal failure requiring dialysis,  
42  
43 blindness and limb amputation in the extreme. The key to its successful treatment is  
44  
45 therefore aggressive and tight control of blood sugar and prevention of ongoing  
46  
47 hyperglycaemia in the tissues. The combined use of metformin and glibenclamide as in  
48  
49 this study provides a multifaceted approach to this, by not only mediating insulin release  
50  
51 but also boosting tissue sensitivity to insulin at the same time.  
52  
53  
54  
55

56  
57 Poor compliance to medication is a huge barrier to effective treatment of diabetes and  
58  
59 has long been researched and acknowledged. This problem is complex and thought to be  
60

1  
2  
3 caused by patient perceived treatment efficacy, medication beliefs, cost of treatment,  
4 treatment complexity and convenience, as well as hypoglycaemia and other unwanted  
5 side effects such as diarrhoea. Diabetes can often be asymptomatic in the initial stages  
6 also affecting attitudes to treatment and medication use. This study could help to combat  
7 many of these aspects by reducing the number of drugs and the number of doses needed  
8 per day, as well as minimising the side effect profiles. This research also tackles the  
9 problem of bioavailability. For example, metformin has an absolute oral bioavailability of  
10 40 to 60%, the drug loaded microparticles designed in this paper would significantly  
11 elevate this percentage and boost drug delivery. The promise of future combined drug  
12 treatments in the depot microparticle form as routine and mass market prescription for  
13 diabetes is an exciting one and further research is needed to facilitate this vision.

31

### 32 *5 Conclusions*

33  
34  
35 In this study, we successfully formed, using electrohydrodynamics, a core/shell  
36 microparticle systems where active drugs, metformin or glibenclamide or a co-  
37 formulation of both drugs, occupied the core of the microparticles while the shell was  
38 entirely made of the polymer polymethylsilsesquioxane. While the individual particle  
39 sizes was influenced more by the electrical conductivity of the inner solution i.e. the  
40 portion forming the core of the particles, particle sphericity and size uniformity within a  
41 batch were to a large extent dependent on the flow rate. Therefore, during the formation,  
42 flow rates were fine-tuned for the best possible shape of particles and uniformly  
43 distributed particles. In terms of molecular composition, FTIR confirmed groups seen in  
44 starting materials to be present particles, thus establishing that products indeed  
45 contained active drugs as was intended during formation. Furthermore, an XRD scan  
46  
47  
48  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 between  $5^{\circ}$  and  $45^{\circ}$  ( $2\theta$  degrees) confirmed the drugs encapsulated within the  
4  
5  
6 microparticles existed predominantly in the amorphous state.  
7

8  
9 At the initial phase of drug release, it was observed that a higher amount of the more  
10  
11 soluble metformin was released compared to the less soluble glibenclamide. This was  
12  
13 expected and largely attributed to the higher water solubility of metformin driving up  
14  
15 diffusion from the microparticle into the dissolution media. Significant initial bursts seen  
16  
17 in all particles were analysed and were most likely caused by drug diffusing through the  
18  
19 shell onto the particle surface through solvent evaporation during particle formation.  
20  
21

22  
23 A mathematical model of the system has been developed, based on the key parameters at  
24  
25 play such as the core/shell structure, extent of partitioning of drugs between these two  
26  
27 layers, dissolution volume and its rate of refreshment. This has allowed a more detailed  
28  
29 understanding of how drugs could be released from a two-layered system. The frequency  
30  
31 of sampling is shown to upset the equilibrium at the interface between the particle and  
32  
33 the release medium; the additional release required to reset this equilibrium has been  
34  
35 shown to significantly influence the overall amount of drug released.

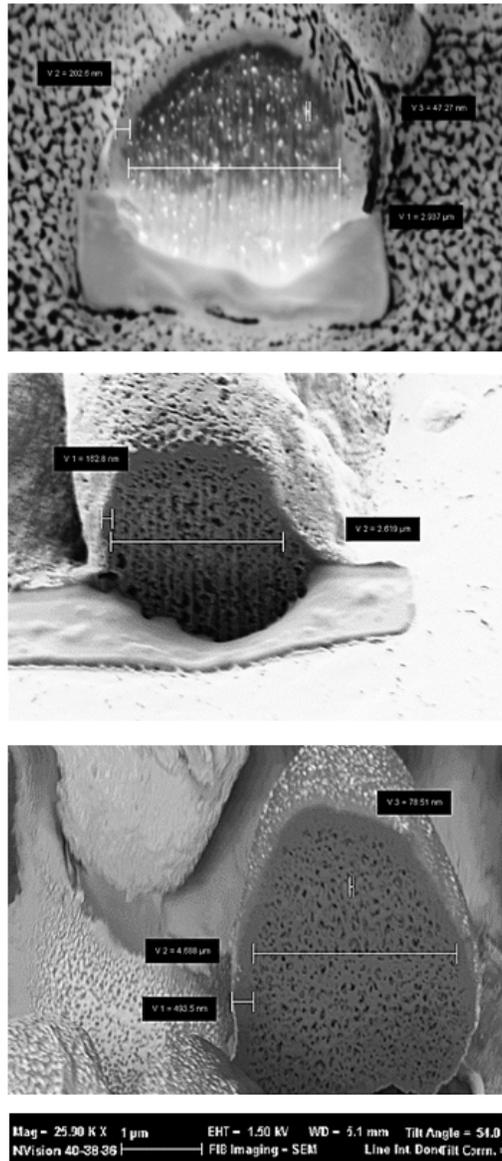

Figure 4 Fig. 5. SEM/FIB cross-section images of the prepared formulations S1, S2 and S3.

96x220mm (96 x 96 DPI)

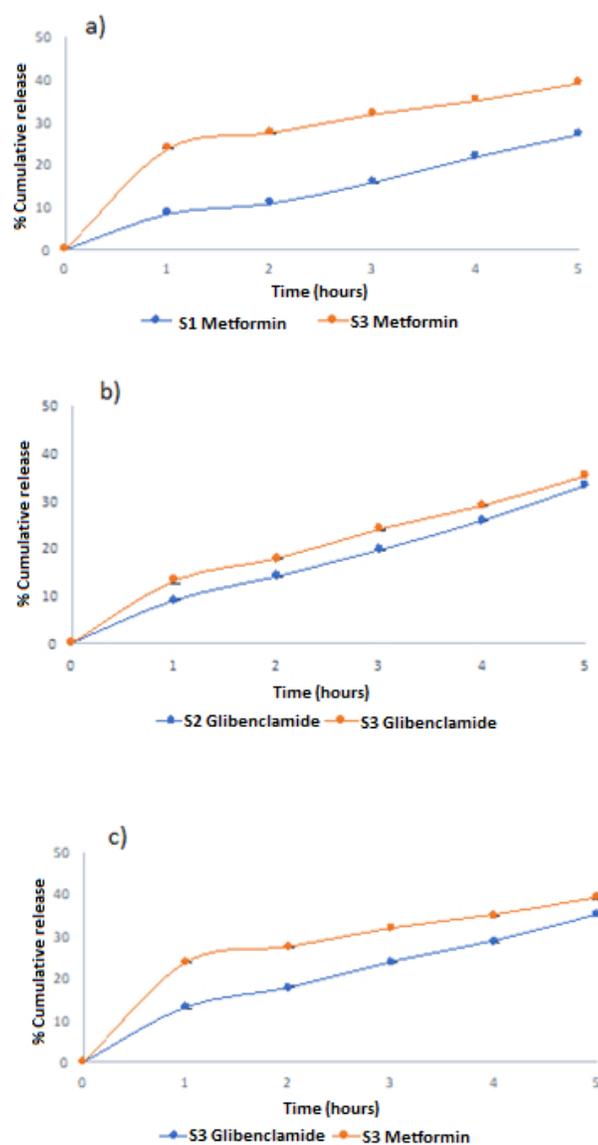

Figure 5: Cumulative drug release in the first 5 hours of a) metformin from S1 and S3 formulations b) glibenclamide from S2 and S3 formulations and c) cumulative release of glibenclamide and metformin percentage cumulative release from S3.

96x187mm (96 x 96 DPI)

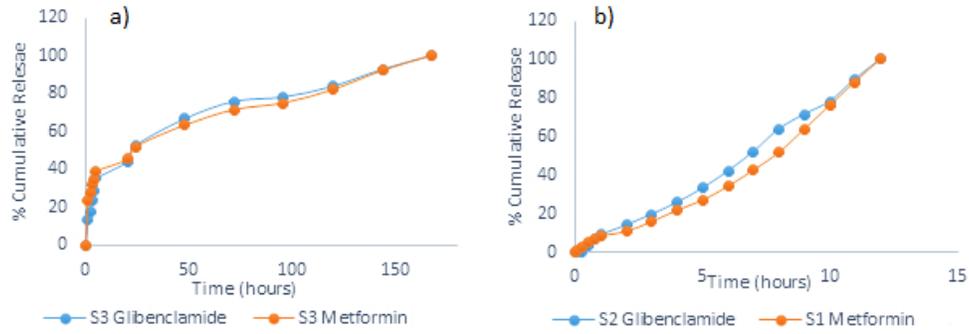

Figure 6 a) Glibenclamide and metformin cumulative release from S3 and b) glibenclamide and metformin cumulative release from S2 and S1.

162x69mm (96 x 96 DPI)

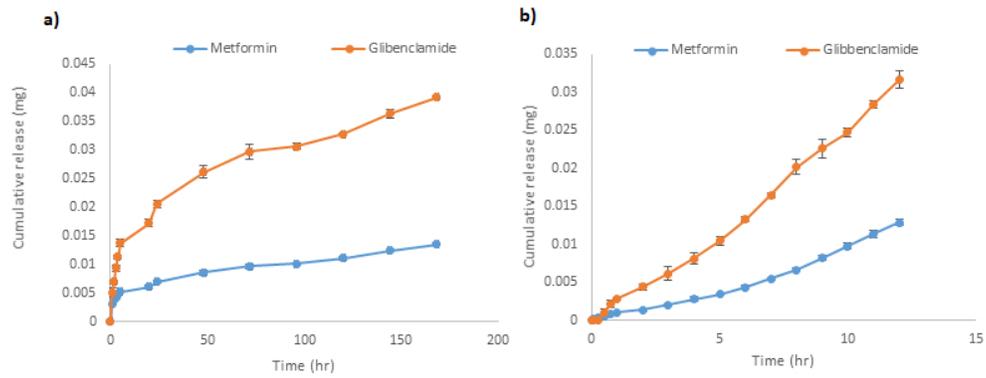

Figure 7: a) Cumulative release of metformine and glibenclamide from microparticles containing both drugs over 7 days and b) cumulative release of metformine and glibenclamide from microparticles containing both drugs over initial 12-hour period.

211x85mm (96 x 96 DPI)

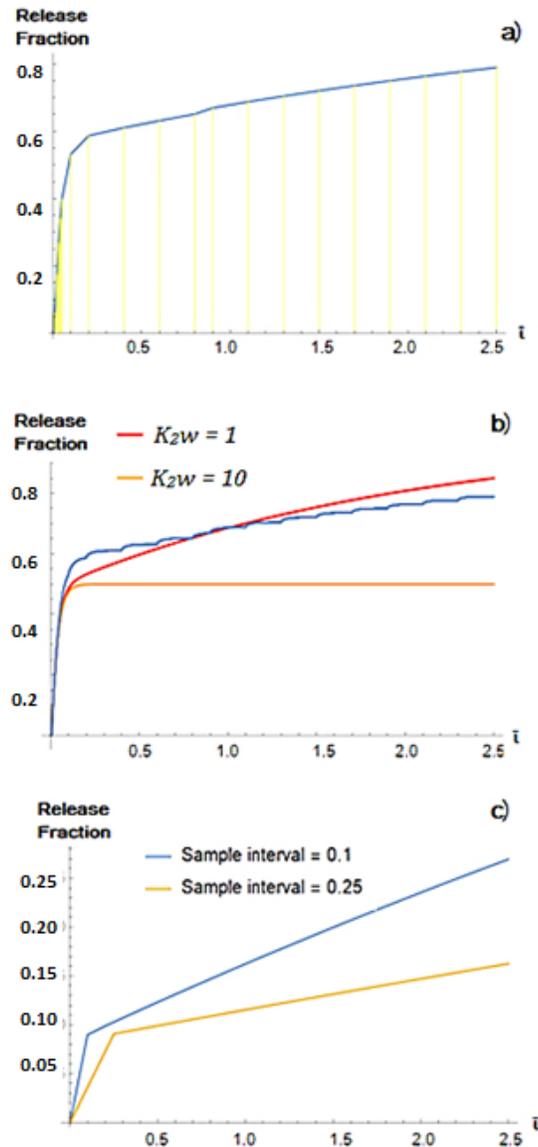

Figure 8: a) Finite difference predictions of the release fraction obtained with sampling for the case  $K_{pw} = 10$  and sample fraction  $f=0.1$ . The yellow vertical lines show the sampling times, b) finite difference predictions of the release fraction obtained with sampling for the case  $K_2w=10$  and sample fraction  $f=0.1$ . The blue line shows the evolution of the release, following every step  $\Delta\tau$  of the calculation. The red line shows the release profile that would be obtained with constant sampling at a rate  $f = 1$ , according to equation 32 (in Supplementary Information), and the orange line shows what would be seen without sampling and c) finite difference predictions of the release fraction obtained with different sampling for the case  $K_{pw} = 10$  and sample fraction  $f=0.1$

87x179mm (96 x 96 DPI)
