ABSTRACT

How does firm entry affect innovation incentives and productivity growth in incumbent firms? Micro-data suggests that there is heterogeneity across industries--incumbents in technologically advanced industries react positively to foreign firm entry, but not in laggard industries. To explain this pattern, we introduce entry into a Schumpeterian growth model with multiple sectors which differ by their distance to the technological frontier. We show that technologically advanced entry threat spurs innovation incentives in sectors close to the technological frontier--successful innovation allows incumbents to prevent entry. In laggard sectors it discourages innovation--increased entry threat reduces incumbents' expected rents from innovating. We find that the empirical patterns hold using rich micro-level productivity growth and patent panel data for the UK, and controlling for the endogeneity of entry by exploiting the large number of policy reforms undertaken during the Thatcher era.

1 Introduction

There is a long standing interest in the effects of firm entry, which are widely recognized as major drivers of economic growth. Entry can induce reallocation of inputs and outputs, trigger knowledge spillovers and affect innovation incentives in incumbent firms. Entry by foreign firms has been a focus of attention in recent years, particularly in countries or industries behind the technological frontier, and has spurred widespread policy reforms aimed at fostering the free movement of goods, services, capital and firm management. Empirical studies on the effects of market liberalizations and foreign direct investment provide, however, mixed results on incumbent reactions.¹ In this paper we take a new look at this issue. We combine theoretical and empirical analysis to investigate a major source of systematic heterogeneity in foreign firm entry effects on incumbent innovation incentives and productivity growth across industries, time and economic environments.

We are motivated by the following empirical regularity - we see substantial heterogeneity in the effects of foreign firm entry on average incumbent total factor productivity (TFP) growth when we look across industries in the United Kingdom (UK). In some industries entry has a strongly positive effect, while in others it seems to depress incumbent TFP growth. Positive effects are found in technologically advanced industries, and weak or even negative ones in technologically laggard industries. This is illustrated in Figure 1, where we plot the foreign entry rate in an industry at time $t - 1$ against the average TFP growth estimate for incumbent establishments in that industry at time t . The sample is split at the median distance to the technological frontier, as measured on the industry level by relative US-UK labor productivity.²

[Figure 1 here]

This finding of heterogeneous entry effects is compelling, but we find no ready explanation

¹See, inter alia, Aitken and Harrison (1999), Pavcnik (2002) and Javorcik (2004) and the literature cited there.

²See notes below figure 1 and section 4 for a description of the data and variables used here.

in the theoretical literature. Our contribution in this paper is first to discuss in detail a theoretical explanation that is consistent with this form of heterogeneity, then to explore the robustness of the finding using micro panel data, and paying particular attention to the problem of entry endogeneity in incumbent performance equations.

Our theoretical explanation comes from a multi-sector Schumpeterian growth model with entry threat that affects the innovative effort by incumbent firms in a systematically different way according to the initial state of technological development in the industry. We focus on technologically advanced entry in the theoretical part of the paper, which accords well with our foreign firm entry measure in Figure 1, since firms that operate internationally are more likely to produce at the technological frontier.³ A main implication of the model is that higher threat of technologically advanced entry should encourage innovation by incumbents in sectors that are initially close to the technological frontier. This escape-entry effect is similar to the escape-competition effect analyzed in Aghion et al. (2001, 2005a). Incumbents that are further behind the frontier have no hope to win against a potential entrant, and therefore the effect of an increased entry threat is to reduce the incumbents' expected payoff from investing in R&D. This discouragement effect is similar to the Schumpeterian appropriability effect of product market competition. The effects of entry on incumbent productivity growth in sectors near and further behind the technological frontier mirror the heterogeneous pattern of entry effects on innovation incentives.

The descriptive evidence provided in Figure 1 is of course not sufficient to establish a causal relationship from entry to incumbent performance, measured by innovative activity or productivity growth. The entry threat variable used in the theoretical model is not observable, and it is endogenous in incumbent performance equations, as we show in greater detail in the paper. Using, as we do, actual entry as a proxy for entry threat, only worsens the endogeneity problem.⁴ To deal with this we exploit as instruments the large number of

³See section 4.2 for details.

⁴The reason is that actual entry deviates from entry threat only in situations where entrants may lose against incumbents and the difference between entry threat and actual entry then depends again on incumbent performance in form of innovative activity.

policy interventions that substantially changed the conditions for foreign entry in the UK during the 1980s and 1990s in different industries at different times. The instruments we use are shown to have a strong influence on foreign entry, conditional on other covariates in the model such as competition and trade. To measure actual entry of foreign firms and separate it out from domestic firm entry for a large number of 4-digit manufacturing industries we can use rich panel data on the population of manufacturing plants and their ownership. We link US and UK data to identify industries that are near or further away from the technological frontier and control for endogeneity of the distance to frontier using US technology and production information as additional instruments. We complement our productivity growth analysis by investigating entry effects on incumbent firms' patenting behavior, which is a more direct measure of innovative efforts. Also, we consider the effects of domestic entry on incumbent performance, and relate these to our theoretical analysis. Finally, we argue why the two most likely alternative explanations based on knowledge spillovers do not explain the full pattern of our empirical findings.

Our theoretical analysis relates to several papers in the theoretical IO literature, in particular Gilbert and Newbery (1982) on preemption, and Laffont and Tirole (1993) on the regulation of entry. Laffont and Tirole analyze the welfare effects of entry regulation in a model of product differentiation. However, they do not allow for incumbent innovation, and concentrate instead on how entry regulation affects the size of innovations, or the extent of differentiation, by newly entering firms. Fudenberg and Tirole (1984) and Tirole (1988) analyze the strategic interaction between entrants and incumbents. Barro and Sala-i-Martin (2004) and Aghion et al. (2005a) focus on competition among incumbent firms and its effects on growth, but they do not consider entry. Recent theory papers focussing on reallocative effects of entry and trade liberalization reforms are Melitz (2003) and Bernard et al. (2003). In contrast, this paper focuses on the way in which entry effects growth through within-firm innovation effects in incumbents.

Our empirical analysis relates to several different strands of empirical work. First, there

is the empirical literature on the effects of trade liberalization and foreign direct investment. Studies including Aitken and Harrison (1999), Pavcnik (2002), and Javorcik (2004) are, as ours, based on plant or firm data and exploit variation of trade and entry across industries and time.⁵ Second, there is an empirical IO literature, following the work of Bresnahan and Reiss (1990, 1991) and Berry (1992).⁶ The emphasis in these papers is on entry in well defined, oligopolistic markets and on endogeneity of market structure. Olley and Pakes (1996) investigate the effects of deregulation on aggregate productivity growth and the underlying reallocation mechanism in one particular industry. We focus instead on the heterogeneity in entry effects on incumbent innovation and productivity growth across markets. Another related strand is the literature on product market competition, firm performance and innovation, in particular Nickell (1996), Blundell et al. (1999), and Aghion et al. (2005a).

More directly linked to this paper, Aghion et al. (2004) analyze entry effects on average incumbent productivity growth and show that industries with higher changes of the employment share in foreign firms experience, on average, higher growth of total factor productivity in incumbents. Aghion and Griffith (2005) provide a summary of recent theoretical and empirical literature on competition, entry and growth.

Our result that entry threat has positive effects on incumbent innovation incentives and productivity growth in industries initially close to the technological frontier, but not in those industries that are initially further behind the frontier, has direct implications for the policy debate on market (de)regulation, competition policy, large scale privatization, and trade liberalization. This debate underlies the consideration of costs and benefits of globalization and the discussion on entry regulation in different countries and industries.⁷ What our analysis suggests is that policies aiming at decreasing or removing entry barriers alone may

⁵Plant or firm level data is also used by Bertschek (1995), Griffith et al. (2002), Haskel et al. (2002), Keller and Yeaple (2004). Aghion et al. (2005b) rely on industry level panel data to analyze the unequalizing effects of delicensing reforms on manufacturing industry performance across states in India.

⁶Recent examples are, among others, Mazzeo (2002) and Seim (2004). Berry and Pakes (2003) provide an excellent overview.

⁷Djankov et al. (2002), for example, present comparative data on direct entry regulation in 85 countries. Bertrand and Kramarz (2002) look at employment effects of entry regulation in the French retail industry. See also Nicoletti and Scarpetta (2004).

not be sufficient to foster productivity growth of incumbent firms in all industries, even when such policies can be shown to be growth-enhancing on average. This, in turn, may suggest complementary policies to facilitate the reallocation of factors and resources from less to more technologically developed industries that react more positively to entry threat. Regulation that inhibits such reallocation should be reduced.

The paper is organized as follows. In section 2 we sketch the key elements of the theoretical model; further theoretical analysis is provided in section 5.3 and Appendix A. We specify the empirical models in section 3 and describe data and variable construction in section 4. Empirical results are presented in section 5 and in section 6 we conclude.

2 A theoretical explanation for heterogeneity in entry effects

To explain the heterogeneous entry effects illustrated in Figure 1 we introduce technologically advanced entry into a multi-sector Schumpeterian growth model.⁸ The model implies that higher entry threat has a positive effect on economic performance of incumbent firms in sectors that are initially close to the technological frontier, whereas it may damage the performance of firms in sectors that are initially further behind the frontier.

2.1 Basic model

In each period t a final good, henceforth the numéraire, is produced under perfect competition using a continuum of intermediate inputs, according to the technology:

$$y_t = \int_0^1 A_t(i)^{1-\alpha} x_t(i)^\alpha di, \quad \alpha \in (0, 1), \quad (1)$$

where $x_t(i)$ denotes the quantity of the intermediate input produced in sector i and $A_t(i)$ is the productivity parameter associated with the latest version of that input.

For each intermediate product there are two firms capable of producing an innovation. Intermediate producers live for only one period, and property rights over their technological

⁸A simplified version of this model with a fixed probability p of entry is sketched in Aghion et al. (2004) and in Aghion and Griffith (2005).

capabilities are transmitted within dynasties. The final good is used as capital in the production of intermediate goods with a one-for-one technology. We assume Bertrand competition within each intermediate sector.

In any sector where both firms have access to the same technology, Bertrand competition implies zero profits. In any sector where one firm (the “leader”) has a better technology than the other (the “laggard”), only the leader will actively produce. As shown in Zilibotti et al. (2005), the equilibrium profit for each leader takes the form:

$$\pi_t(i) = \delta A_t(i), \quad \delta = (1 - \alpha)\alpha^{\frac{1+\alpha}{1-\alpha}}. \quad (2)$$

2.2 Technological states, innovation, and entry

The world’s “technological frontier” at the *end* of each period t is characterized by a technology parameter \bar{A}_t which grows at the exogenous rate $\gamma - 1 > 0$:

$$\bar{A}_t = \gamma \bar{A}_{t-1}.$$

At the *beginning* of period t intermediate firms can be of three types. Firms of type 1 operate at the current frontier, with a productivity level $A_{t-1}(i) = \bar{A}_{t-1}$. Type-2 firms are one step behind the frontier, with $A_{t-1}(i) = \bar{A}_{t-2}$, and type-3 firms are two steps behind, with $A_{t-1}(i) = \bar{A}_{t-3}$.

Innovation allows an incumbent firm to increase its productivity by the factor γ and thereby to keep up with growth of the frontier.⁹ The cost of technology adoption is quadratic in its hazard rate and also proportional to the targeted level of productivity. More specifically, by incurring a cost

$$c_{jt} = c \cdot (z^2/2) \bar{A}_{t-j}, \quad c > 0,$$

⁹The assumption of “step-by-step” technological progress is made here for the sake of tractability. As in Aghion et al. (2001), this assumption avoids having to deal with asymmetries in the decision problems of firms at different distances from the technological frontier. If we allowed innovating type-2 firms to catch up with the frontier with sufficiently high probability the discouragement effect of entry on type-2 firms would turn into an escape-entry effect. In that case, our model would predict higher rates of innovation and productivity growth for type-2 firms than for type-1 firms, a prediction which is not borne by our data and empirical analysis.

at the beginning of period t , a type- j incumbent, where $j \in \{1, 2\}$, can increase its productivity with probability z by the factor γ within that period, adopting the next most productive technology. With probability $1 - z$ the incumbent's productivity does not increase, and lags by $j + 1$ steps behind the new frontier. The most backward (type-3) firms are automatically upgraded by the factor γ as in Aghion et al. (1997). This reflects the idea that the cost of technological adoption becomes negligible for sufficiently mature technologies.

In each period and intermediate sector, there is one outside producer that can pay for an entry opportunity. We focus on technologically advanced entry; thus when entry occurs it takes place at the *new* frontier \bar{A}_t .¹⁰ An entrant will steal all the market and become the new leading firm unless the incumbent leader also has the frontier technology \bar{A}_t after the innovation process described above, in which case we assume that the incumbent retains the entire market.¹¹

Note that incumbent laggards will never invest in innovation, because an innovation would at best allow the firm to catch up to its rival and would still leave the firm with zero profits. Note also that in steady state there are no intermediate sectors in which the incumbents are both type-1 or both type-2. This is because such a (“level”) sector would have to have been level in the previous period, since non-innovating laggards never catch up to their leader, whereas innovation and entry will eventually unlevel the sector.

Thus, in the long run, all intermediate sectors will be in one of only three possible “states” at the beginning of any period: (a) state-1 sectors are those with a type-1 leader; (b) state-2 sectors are those with a type-2 leader and (c) state-3 sectors are those with two type-3

¹⁰More generally, one can think of several potential entrants with heterogeneous and a priori uncertain productivities, who are racing for entry into a particular industry. As long as at least one potential entrant has a high productivity realization \bar{A}_t , the analysis and comparative static results will remain the same as if we assume only one potential entrant with productivity \bar{A}_t . See section 5.3.2 for a discussion of other forms of entry.

¹¹Aghion et al. (2005c) use the following sequential game between incumbent firms and potential entrants to provide foundations for this assumption. The entrant must pay a small entry fee to enter and can decide whether to pay this fee after observing the post-innovation technology of the incumbent. Assuming that Bertrand competition takes place after entry, the entrant will find it profitable to pay the entry fee and appropriate the local market if the incumbent is expected to lag behind the entrant. If the incumbent is, instead, expected to compete on an equal footing with the entrant, then the entrant will find it optimal not to pay the entry fee.

incumbents.

2.3 Equilibrium innovation

Consider the R&D decisions of incumbent leaders in state-1 and state-2 sectors.¹² Denote by p_j the probability that the potential entrant pays the cost of entry in a state- j sector. This probability depends negatively upon a common entry cost parameter Λ : $p'_j(\Lambda) < 0$ (see Appendix A.1).

- A state-2 leader, with $A_{t-1}(i) = \bar{A}_{t-2}$, chooses its investment z to maximize the expected net profit gain from innovation minus the R&D effort cost, that is:

$$\max_z \{ \delta z (1 - p_2) \bar{A}_{t-1} - c (z^2/2) \bar{A}_{t-2} \},$$

from which the first order condition yields:

$$z = (\delta/c) (1 - p_2) \gamma = z_2.$$

In words, the type-2 leader only retains the market if it successfully innovates and there is no entry (i.e. with probability $z(1 - p_2)$). If it does not innovate then its automatically upgraded type-3 rival catches up with it, and Bertrand competition between the two neck-and-neck firms dissipates all profits.

- A state-1 leader, with $A_{t-1}(i) = \bar{A}_{t-1}$, chooses its innovative investment to:

$$\max_z \{ \delta [z \bar{A}_t + (1 - z) (1 - p_1) \bar{A}_{t-1}] - c (z^2/2) \bar{A}_{t-1} \}.$$

Hence, from the first order condition we get:

$$z = (\delta/c) (\gamma - 1 + p_1) = z_1.$$

In words, the type-1 leader retains the market when: (i) it successfully innovates or (ii) it does not successfully innovate and there is no entry.

¹²Recall that laggards do not innovate and type-3 firms are automatically upgraded without investing.

2.4 The “escape entry” and “discouragement” effects

Now consider the effects of increasing entry threat on innovative activity, which we here model as a reduction in the entry cost parameter Λ . In state-3 sectors an increase in the entry threat has no effect on innovation investments, since those are always equal to zero. Now, consider what happens in state-2 and state-1 sectors:

- In state-2 sectors, a reduction in Λ that increases the entry threat $p_2(\Lambda)$, reduces the expected payoff from innovating and therefore “discourages” innovation. Firms further behind the frontier know that they cannot survive entry, even if they successfully innovate. That is:

$$\frac{\partial z_2}{\partial \Lambda} = -(\delta/c) \gamma p_2'(\Lambda) > 0. \quad (3)$$

This *discouragement effect* is similar to the Schumpeterian appropriability effect of product market competition pointed out, for example, in Aghion et al. (2001, 2005a).

- In state-1 sectors, a reduction in Λ that increases the entry threat $p_1(\Lambda)$, fosters innovation as it increases the incumbent leaders’ losses from entry if they do not innovate, thereby increasing their incentive to “escape entry” by innovating. That is:

$$\frac{\partial z_1}{\partial \Lambda} = (\delta/c) p_1'(\Lambda) < 0. \quad (4)$$

This *escape-entry effect* is similar to the escape-competition effect pointed out in Aghion et al. (2001, 2005a).

Together with the fact that laggards never innovate, this implies that an increase in the threat of entry discourages innovation in a state-2 sector and encourages it in a state-1 sector. Expected productivity growth in either sector is proportional to innovative investment:

$$E \left[\left(\frac{A_t(i) - A_{t-1}(i)}{A_{t-1}(i)} \right) \middle| A_{t-1}(i) = \bar{A}_{t-j} \right] = z_j(\gamma - 1) = g_j, \quad j \in \{1, 2\}. \quad (5)$$

Therefore a reduction in entry cost Λ has a positive escape-entry effect on incumbent productivity growth in state-1 sectors, and a negative discouragement effect in state-2 sectors:¹³

$$\frac{dg_1}{d\Lambda} = \frac{dz_1}{d\Lambda}(\gamma - 1) < 0; \quad \frac{dg_2}{d\Lambda} = \frac{dz_2}{d\Lambda}(\gamma - 1) > 0.$$

2.5 Empirical implications

In summary, the main empirical implications that we draw from the theory are:

- *Increasing the threat of entry has a positive effect on incumbent innovation in sectors that are close to the technological frontier and a possibly negative effect in sectors that are further behind the frontier.*
- *Increasing the threat of entry has a more positive effect on incumbent productivity growth in sectors that are closer to the technological frontier than in sectors that are further behind the frontier.*

3 Empirical specification

The implications derived above explain a heterogeneous pattern of entry effects on incumbent performance along the distance to technological frontier. The descriptive evidence in Figure 1, however, is not sufficient to establish a causal relationship. The central empirical relationship that we want to explore is of the form:

$$Y = f(P, D, X), \tag{6}$$

where Y is a measure of incumbent performance, P is entry threat, D is the distance to the technological frontier, and X is a vector of further covariates. These covariates may determine the performance of incumbents in addition to entry - most important, we think of

¹³In state-3 sectors an increased entry threat does not affect the rate of productivity growth. Being upgraded with probability one, both firms in such sectors grow at the same constant rate $\gamma - 1$. Thus:

$$g_3 = \gamma - 1,$$

and a reduction in entry cost Λ has no effect on productivity growth.

effects triggered by trade relations and other factors that affect competition, market structure and the rents of incumbents.

Our main measure of incumbent performance is growth of total factor productivity (ΔTFP_{ijt}) measured on establishment level. To bring equation (6) to the data we specify the relation between incumbent TFP growth and entry as

$$\Delta TFP_{ijt} = \alpha + \beta_1 E_{jt-1} + \beta_2 D_{jt-1} + \beta_3 E_{jt-1} D_{jt-1} + X'_{ijt-1} \gamma + \tau_t + \eta_i + u_{ijt}. \quad (7)$$

where i indexes incumbent establishments, j indexes industries, and t indexes years. While entry threat P is unobservable, actual entry E and variables affecting entry costs Λ can be observed. We use lagged actual entry E_{jt-1} directly in equation (7) and instrument it with policy reforms that change entry costs Λ building on the following economic reasoning. If entry threat were observable and we could use it directly in equation (7) it would be potentially endogenous, i.e. depend on incumbent innovation that triggers productivity growth (see equation (11) in Appendix A.2). When using observable actual entry as proxy for entry threat we face the same problem, only in aggravated form. Actual entry deviates from entry threat in situations where entrants may lose against incumbents, that is, in our context, in industries close to the frontier. In industries further behind the frontier, where entrants can never lose against incumbents, actual entry and entry threat are identical (see equation (13)). If entry threat and actual entry differ, then the difference depends again on incumbent innovative activity (see equation (14)). It can be shown that entry threat correlates positively with actual entry as long as incumbent innovation aiming at escaping entry is not too successful in the sense of entry prevention to outweigh the direct positive effect of entry threat on actual entry (see Appendix A.2).

Due to the described endogeneity problem we expect a negative covariance between actual entry and the error term in incumbent performance equations. Including establishment-specific fixed effects and time effects is unlikely to be sufficient to address the endogeneity issue, since industry-specific, time-varying changes of incumbent performance should affect actual entry. Even using a lagged entry measure, as we do, may not fully solve the problem.

Our preferred approach is to control for endogeneity by using selected policy reforms as instrumental variables (IV). We argue that these reforms changed entry costs and effected entry threat as well as actual entry differentially across industries and time but, *conditional* on all other covariates in the model, do not effect TFP growth or innovation. The policy instruments include time-varying indicators of the implementation of the EU Single Market Program (SMP) in industries with medium or high entry barriers that were likely to be reduced by the SMP, competition investigations by the UK Competition Authority that culminated in entry-inducing remedies, and large scale privatizations.¹⁴

Potential endogeneity of the distance to the technological frontier is also a concern since any assumption we impose on that variable can directly affect findings on heterogeneous entry effects along the distance to frontier. To address this issue we use US technology and production information as additional instruments.¹⁵

Our preferred specification of equation (7) includes linear terms of the entry and distance to frontier measures, as well as their continuous interaction term. We show that our results are robust to using alternative functional forms in section 5 (specifically, interacting entry with discrete distance to frontier indicators). To control for different permanent levels of TFP growth across establishments we include individual fixed effects η_i . Common macro shocks are captured by time dummies τ_t .

A concern about using TFP growth in incumbent establishments in our context is that it may not only reflect firms' innovative activity, but also advances due to imitation of entrants with superior technology or reallocation within establishments. To check whether our TFP growth results are likely to pick up actual changes in firms' innovative activity we also estimate patent count models to complement our TFP growth estimations. We specify the innovation rate as

$$n_{ijt} = e^{\alpha + \beta_1 E_{jt-1} + \beta_2 D_{jt-1} + \beta_3 E_{jt-1} D_{jt-1} + X'_{ijt-1} \gamma + \tau_t + \eta_i}, \quad (8)$$

¹⁴A full description of the policy instruments are given in Table B.1, App. B.

¹⁵Summary statistics on these variables can be found in Table B.4, App. B.

where i indexes incumbent firms, j indexes industries, and t indexes years. The patent process is assumed to follow a flexible negative binomial distribution with hazard rate n_{ijt} . All other variables and parameters are defined as in equation (7), and the specification is similar. To take unobservable firm-specific, time-invariant heterogeneity in patent behavior into account we follow Blundell et al. (1999) and use pre-sample information on firms' knowledge stocks.

In the linear model in (7) we apply IV estimation that involves three first stage regressions: one for the linear entry term, one for the distance term as well as one for their interaction. In the non-linear case of (8) we use the control function approach to control for endogeneity. This approach consists of including the three first-stage residual terms in the regression equation.¹⁶

Our identification strategy rests on using actual entry directly in equations (7) and (8) and instrumenting it with policy interventions that affected the ease and cost underlying entry threat and actual entry, and did so differentially across industries and time. For example, the aims of the SMP were to bring down EU internal barriers to the free movement of goods, services, capital and labor by interventions such as harmonizing product standards, indirect taxes and border controls, removing national requirements and other non-tariff barriers that enable firms to segment markets and limit competition, removing public sector discrimination in favor of its own firms, reducing capital and labor costs by permitting free flow across countries. The interventions may also affect innovation incentives and productivity growth through other channels, especially through changing the competitive environment. Thus, we pay careful attention to controlling for measures of competition and import penetration, and argue that the entry instruments have no additional impact on innovation and TFP growth, *after* we condition on these covariates. We test the overidentification assumptions and experiment with using only subsets of these instruments. In section 5 our results are shown to be robust to these specification checks.

¹⁶In linear models, control function and IV coefficient estimates coincide. See Wooldridge (2002), Chapter 18 or Blundell and Powell (2003).

4 Data

We combine micro-level data from several sources. To measure entry we use data on the population of manufacturing plants in Great Britain provided by the UK Office for National Statistics (ONS) in connection with the Annual Respondents Database (ARD). The ARD is the most comprehensive establishment-level dataset for Great Britain and is collected by the ONS under the 1947 Statistical Trade Act. This makes it a legal obligation for firms to report. Time-varying ownership information allows us to quantify firm entry into the UK at the 4-digit industry level. To measure growth of total factor productivity we can use information on output and inputs for the random stratified ARD *sample of establishments* from the population.¹⁷

We also use firm-level accounting data from DataStream that is matched to patent data from the NBER/Case Western Patent database for a *sample of firms* listed on the London Stock Exchange (LSE). Using data on patents at the US Patent Office has the advantage of focusing on major patents by UK firms, since their low value patents are usually not taken out in the US. The firms in our sample account for a large proportion of UK R&D activity.¹⁸

4.1 Total factor productivity growth and innovation

To calculate TFP growth we apply a standard factor share approach, use superlative index measurement (Caves et al. 1982a, b), and data from the ARD on output and inputs of establishments in 180 4-digit manufacturing industries between 1987 and 1993. We pay attention to a number of potential measurement errors in TFP (see Appendix B) and present results using two alternative TFP growth measures as well as labor productivity growth. We also consider a patent count variable as an additional measure of performance. The data set on firms listed on the LSE and their patenting activity at the US Patent Office covers 60 different 3-digit manufacturing industries between 1987 and 1993.

¹⁷About 76 percent of all sampled establishments between 1980 and 1993 are single plants, all others represent groups of on average 1.6 plants operating in the same 4-digit industry and owned by the same firm.

¹⁸See also Appendix B on data sources.

4.2 Entry

When calculating entry measures we can distinguish between foreign firm and domestic firm entry. Our measure for technologically advanced entry as focussed on in the theory section is the foreign firm entry rate. We choose foreign entry since it is from firms that operate internationally and most likely produce at the technological frontier. Moreover, foreign firm entry is an important form of entry in the UK during the 1980s and 1990s. Inflows of foreign direct investment were substantial during that period, and the employment share in foreign owned manufacturers rose from 9.97 in 1980 to 16.14 percent in 1993. We define the foreign firm entry rate as the share of industry employment that is in foreign firms entering the respective British industry for the first time with a newly set-up production facility:

$$E_{jt} = \frac{\sum_{i=1}^{N_{jt}} L_{it} * D_{ijt}(\text{new facility}; \text{owner} = \text{foreign, new})}{\sum_{i=1}^{N_{jt}} L_{it}}, \quad (9)$$

where L_{it} is the number of employees in plant i in year t . The function $D(\cdot)$ equals one if a foreign firm enters industry j with a *new* plant in year t and does *not* own any older plants in industry j , and zero otherwise.¹⁹ The denominator is the number of employees in all plants in industry j at time t . For the productivity growth models we use the measure at the 4-digit industry level (SIC code) and for the patent count models at the 3-digit SIC code level.

The domestic firm entry rate is calculated in a similar manner and its effects on incumbent productivity growth and patenting activity are investigated in section 5.3.2.

Our entry measures capture the size of foreign or domestic entry and thus go beyond simply counting entrants or simply considering all entering firms in one measure. The foreign firm entry rate, moreover, is a more direct entry measure than macro data on cross border financial flows, which are often used to measure FDI. In contrast to micro-data measures based on the share of industry employment in all foreign-owned production units²⁰ our

¹⁹If a foreign firm enters industry j simultaneously with more than one new plant in year t then employment in all these plants is counted, but any form of firm expansion after the year of entry is excluded.

²⁰See, for example, Aghion et al. (2004), Griffith et al. (2002) and Haskel et al. (2002).

measure focuses precisely on entry and separates it out from employment expansion or contraction of existing foreign firms and from reallocation between domestic and foreign owners via takeover activity.

4.3 Distance to frontier

We measure the distance of each UK industry to the industry-specific technological frontier using two alternative metrics for technology. In the context of the productivity growth models we use disaggregated measures where each 4-digit UK industry is compared to a matched 4-digit US industry.²¹ For the patent count models we use disaggregated measures on the 3-digit SIC code level. Our main measure for UK industry j in year t is the relative labor productivity measure

$$D_{jt} = \frac{1}{3} \sum_{z=0}^2 \ln \frac{(Y^{US}/L^{US})_{jt-z}}{(Y^{UK}/L^{UK})_{jt-z}},$$

where Y denotes real output and L employment. Since we observe output and input data for the pre-sample period we can use a lagged three year moving average to mitigate the effects of measurement error on the time variation of the distance variable. The second measure we use is a superlative index relating TFP in each US industry to TFP in the corresponding UK industry. Our empirical results in section 5 are shown to be robust to introducing this second measure and to instrumenting both distance to frontier variables. Results are also similar if we use and instrument discretised versions of the continuous distance variables where we simply group industries close to and far from the technological frontier.

US industries are chosen as a reference point for the following reasons - the US represents the technological frontier in a large number of industries, it is often ahead of the UK,²² and a large share of foreign entrants in Britain are US-owned.²³ To calculate the distance to frontier measure we matched data on US 4-digit industries from the NBER manufacturing

²¹See App. B for details on the matching of UK and US industries.

²²See, inter alia, Griffith et al. (2004).

²³For the time period 1986 to 1992 our data shows that, on average, 34 percent of all foreign greenfield entrants in British manufacturing industries are under US ownership.

productivity database and the ARD data on domestic incumbent establishments in Britain aggregated to the 4-digit industry level.²⁴

British 4-digit industries differ considerably in their distance to the industry-specific frontier as illustrated in Table B.2, App. B. The table lists the 10 largest industries above and below the median distance to frontier. The sample distribution of the distance measure is such that about 20 percent of all industry-year observations are at or close to the frontier, while another 20 percent of industries are more than 40 percent behind their US counterpart. In the context of our study, high variation of the distance measure is crucial given our interest in heterogeneity of entry effects along the distance to frontier distribution.

Another important prerequisite for our empirical analysis is variation of entry rates across industries with different distance to the industry-specific frontier. We checked that all four quartiles of the distance distribution cover industry-year observations where no, some or substantial foreign entry occurs. In addition, comparing the quartile-specific distributions of the entry rate, the number of employees in entering firms and entrants' size we see in Table B.3, App. B considerable overlap of these distributions.

4.4 Descriptive statistics

Our sample for the estimation of productivity growth models is an unbalanced panel of 23,802 observations on 4,947 domestic incumbent *establishments* in 180 4-digit industries, 1987 to 1993.²⁵ 81 percent of these establishments are older than 10 years when they enter the sample. They have on average 274 employees, real output of £15m in 1980 £, and experience TFP growth of on average -0.8 percentage points. This negative average growth reflects the recession in the early 1990s; the corresponding figure up to 1990 is 1.3 percentage

²⁴App. B provides details on the matching of UK and US industries. The ARD and NBER databases contain data collected by national statistical agencies in each country using similar methods, and the data on value-added and numbers employed use very similar definitions (see App. B for references). To the extent that the definitions may vary across countries, this should be controlled for by industry and time fixed effects. We use labor productivity as our main measure as this is not affected by differences in the way capital is measured across the two datasets. However, we show that our results hold when using a TFP-based measure (see section 5).

²⁵See Appendix B on sample construction.

points.

To estimate the patent count models we use an unbalanced panel of 1,085 observations on 176 incumbent *firms* in 60 3-digit industries, 1987 to 1993. 74 percent of the firms were listed on the LSE for more than a decade when entering the sample. They employ on average about 8,549 people, have average real sales of £443m in 1980 £ and about 60 percent take out at least one patent at the US Patent Office between 1987 and 1993. As typically found, the distribution of patent counts is highly skewed - many firms in our sample do not patent, some patent a little and a small number of firms are granted many patents per year.

Further details on data sources, sample construction and descriptive statistics are given in Appendix B.

5 Empirical results

To investigate the economic mechanism behind the descriptive evidence in Figure 1 we estimate productivity growth, as well as patent count models, where we control for confounding factors and take endogeneity of entry and distance to frontier measures into account. Then, we analyze how measurement issues and the key theoretical assumption on entry affect our results. We conclude by explaining why the most likely alternative interpretations based on knowledge spillovers do not fully explain our empirical findings.

5.1 Growth of total factor productivity

To start with, we analyze the average effect of entry on subsequent total factor productivity (TFP) growth among incumbents in more restrictive models than equation (7). All regressions in Table 1 include a full set of year and establishment-specific fixed effects. Standard errors are clustered on the industry level and observations are weighted by employment and the inverse of their sampling probability.²⁶

²⁶See Moulton (1990) on standard error clustering. Observation weights and the sampling scheme are described in Appendix B.

[Table 1 here]

In column (1) we use a linear term of the lagged foreign firm entry rate (as defined in section 4.2) and find a positive and significant effect on subsequent TFP growth of domestic incumbent establishments. We checked that the coefficient of the entry rate is driven by changes in the number of new employees in entering foreign firms, rather than changes in the number of all employees in the industry.²⁷

In column (2) we include three additional covariates - distance to the frontier, import penetration and competition - and show that the average entry effect is robust to controlling for these factors. High values of the lagged distance measure indicate industries that are far from the industry-specific frontier (see section 4.3 for the distance definition). The positive and significant coefficient indicates higher growth rates for domestic incumbents in industries that are far from the frontier than in those close to it. We will return to this result in section 5.3.3.

Foreign firms can enter local product markets through imports, as well as by building up local production capacity. We pay less attention to this alternative form of entry, mainly because we have much less disaggregated import data. We control for lagged import penetration and find a positive and significant effect on subsequent TFP growth in domestic incumbent establishments, however, it has little impact on the coefficient of foreign firm entry. To capture the influence of other rent-affecting processes we use the lagged rent-based competition measure described in Appendix B. It is calculated at the 4-digit industry level, varies between 0 and 1 and takes the value of 1 in case of perfect competition. In line with previous work, inter alia Nickell (1996), we find a positive and significant coefficient.

In columns (3) and (5) we address the core endogeneity issues. As stated above, we expect a negative covariance between actual foreign firm entry and the error term in our TFP growth model, since foreign firms can more easily realize entry into markets when their

²⁷In a regression with both elements of the entry rate included separately the coefficient (*standard error*) of the numerator, the number of entering employees, is positive and significant (0.017 (0.005)) while the coefficient of the denominator is small and insignificant (0.0003 (0.0002)).

relative advantages are high and they anticipate this correctly. This is where productivity growth and innovative activity of incumbents is weak and, thus, their chances to escape and prevent entry are small. Note here, that the opposite expectation is often expressed, but not confirmed in the literature of foreign direct investment: Foreign entrants may be attracted by high growth perspectives of domestic incumbents and anticipate these correctly such that a positive covariance between the entry variable and the error term in incumbent performance equations would result. Attenuation bias (towards zero) in an OLS regression could also be caused by measurement error. In the IV regression in column (3) we use as instruments variables on product market policy changes that influence entry costs and, thus, effected entry threat and actual entry differentially across industries and time (see also section 3). Statistics from the first stage regression of entry on the excluded policy instruments and all other exogenous variables are shown at the bottom of Table 1.²⁸ The instruments are powerful, the F-test indicates their joint significance.²⁹ No rejection of the overidentifying restrictions is implied by the χ^2 -test result, and this also provides statistical support for the overall set of policy instruments. We can show that the significant, positive entry effect is stable with respect to many changes of the model specification and the set of instruments.³⁰

The F-test for the exogeneity of the entry term rejects the exogeneity of actual foreign firm entry and highlights the importance of instrumenting. Since the IV coefficient on the

²⁸In all first stage regressions we impose the same coefficient for all individual monopoly cases where the coefficients were not statistically different from each other in intermediate versions of the first stage regressions. Analogous restrictions are used in case of merger, privatization and SMP indicators. In addition, we aggregate highly correlated policy dummies that relate to the same industry. The first stage entry regression in column (3), thus, includes 11 separate instrumental variables.

²⁹When calculating standard errors and test statistics we take into account that our dependent variables in first stage regressions are measured at the industry level.

³⁰For example, if we exclude all privatization instruments, we find the following entry coefficient (*standard error*): 2.896 (*0.292*). When, in turn, excluding the instruments that belong to one of the other groups of policy changes (monopoly cases, merger cases, SMP introduction) the entry coefficients are all positive, significant and quite stable. They vary between 2.920 (*0.362*) and 3.841 (*2.102*). In all four model variants with reduced instrument sets, these sets are jointly significant on the first stage and overidentification tests never reject.

When we change the model specification to include industry-specific instead of establishment-specific fixed effects the entry coefficient (*standard error*) is: 3.089 (*0.314*). When controlling for lagged establishment-specific sales market shares instead of using the rent-based competition measure the entry effect estimate is: 2.642 (*0.275*).

foreign firm entry rate is larger than the OLS estimate, a negative bias is found, and this is in line with our expectation of a negative covariance between entry and the error term in our TFP growth model. It may also reflect an attenuation bias (towards zero) in the OLS regression caused by measurement error.

The positive average impact of the direct foreign entry measure we use here on incumbent TFP growth is in line with the results we find in Aghion et al (2004). There we use British data for a longer time period and a less direct, noisier entry measure, i.e. the change of the industry employment share in all foreign firms, not only in entrants.³¹ Our finding is also consistent with the average incumbent productivity growth prediction that can be derived from our theoretical model for plausible parameter assumptions (see Appendix A.3). However, it is important to note that this is neither an unconditional implication of the theory set out in section 2, nor is it in line with the empirical evidence from several studies of foreign direct investment or liberalization reforms.³²

Thus, we allow for more flexibility in the relation between foreign firm entry and productivity growth to see whether there is systematic heterogeneity of entry effects along the industry- and time-varying distance to the industry-specific technological frontier. To do this we estimate equation (7) including the continuous interaction of the entry and distance to the frontier measures.

When including the interaction term, the coefficients of the linear entry and distance terms in column (4) remain positive and significant, as before. The interaction is negative and significant. In industries that are far away from the frontier the positive effect of entry is now counteracted by the negative interaction effect. Thus, productivity growth of domestic incumbents responds more positively to technologically advanced entry in industries close to the technological frontier than in industries farther below the frontier and this provides first support for the second empirical implication from the theory in section 2.

³¹See also Griffith et al. (2002) and Haskel et al. (2002).

³²For example, Javorcik (2004) and Aitken and Harrison (1999).

Similar results arise when we control for endogeneity of entry and the distance to frontier in column (5). We now have three first stage regressions, one for the linear entry term, one for the linear distance term and one for the interaction term. Taking potential endogeneity of the distance measure into account is important since any assumption we impose on that variable directly feeds into our main finding of heterogeneous entry effects. In addition to policy instruments we use as further instruments measures of the production and technology structure in US industries that are significantly correlated with the distance measure, but which can be assumed not to depend directly on anticipated UK TFP growth developments. We identify two such variables: the capital-labor ratio and average real wages among skilled workers in US 4-digit industries at the beginning of the time period relevant for distance measurement.³³

The F-tests in the bottom panel of Table 1 shows that the set of instrumental variables has explanatory power in all three first stage regressions. The χ^2 -test indicates no rejection of the overidentifying restrictions. The F-test of joint exogeneity of all instrumented terms in the second stage regression is rejected and, thus, taking endogeneity into account matters. We find a negative and significant interaction term in column (5) and positive and significant coefficients on the linear terms for entry and distance to frontier. Again we can show that the results are stable with respect to changing the model specification as above and varying the set of instruments.³⁴

The estimation results above strongly indicate heterogeneity in the impact of foreign firm entry on subsequent TFP growth in domestic incumbent establishments, depending

³³To capture the effect of US technology on the distance of UK industries to the frontier we also tried research and development intensities in 2-digit US industries and the US ratio of skilled over all workers in 4-digit industries. However, both these variables turned out to have no explanatory power in first stage distance regressions. This finding deviates from what we find in the firm sample used for patent count models below.

³⁴Most important, we find stable results if we vary the main instrument set by excluding in turn privatization, monopoly, merger or SMP instruments. The second stage estimates for the linear entry coefficient then vary between 3.864 (2.544) and 4.823 (1.621) and those for the distance term between 0.077 (0.051) and 0.088 (0.043). The interaction estimates take values between -8.387 (3.111) and -10.957 (7.751). In each model, both entry-related coefficients (linear and interacted) are jointly significant at the 1%-significance level. Moreover, the reduced instrument sets are always significant on the first stage and overidentification tests never reject.

on the industry’s distance to the frontier, and a positive average impact. But what about the economic significance of these effect estimates? To see that we calculate the impact of increasing the entry rate by one standard deviation in the sample (0.5 percent) on subsequent incumbent TFP growth at the 10%, 50% and 90% percentile of the sample distance to frontier distribution. In industries at the median distance to frontier an increase of the foreign firm entry rate by one standard deviation raises TFP growth in domestic incumbent establishments by 1.4 percentage points.³⁵ In industries far from the frontier, i.e. at the 90%-percentile of the distance distribution, the TFP growth effect is -0.3 percentage points and close to the frontier (10%-percentile) the effect is 3.1 percentage points. Since the mean of TFP growth in the sample is -0.8 percentage points, and the standard deviation is 11.3 percentage points, these estimates are economically significant and their variation along the distance to frontier distribution is reasonable. All in all, the results in columns (4) and (5) of Table 1 consistently show that the threat of technologically advanced entry in industries close to the frontier triggers subsequent TFP growth among incumbents and can discourage it in industries far from the frontier.

5.2 Patenting

The TFP growth evidence shown above provides support for the idea that entry spurs incumbents to invest in innovation, particularly when they are near the technological frontier. Lingering concerns are, however, that TFP growth may not only reflect entry-induced innovative activity, but also entrant imitation or that TFP growth may be driven by reallocation between plants within incumbent establishments. In order to explore the relation between entry and innovation more directly we estimate patent count models that are specified in a similar manner as the TFP growth models. While using an entirely different dataset to measure firm-level innovation (see section 4) we find a strikingly similar pattern of results.

³⁵This median effect based on column (5) is equal to the average effect since the sample distance distribution is unskewed. Moreover, the result of 1.4 is similar to the impact of 1.5 that is implied by the model in column (3) with a linear entry term only.

[Table 2 here]

In Table 2 we present estimates from negative binomial models that allow for overdispersion of the patent count variable and include time as well as 3-digit industry fixed effects. We capture unobservable firm-specific, time-invariant heterogeneity of patenting behavior by exploiting rich pre-sample patent data. Following Blundell et al. (1999) we add as explanatory variables two proxies for a firm's technological knowledge stock: the firm-specific pre-sample patent stock and an indicator for non-zero pre-sample patent stock values. As expected, the coefficients on both these variables are found to be significant and positive.

In line with what we find in the TFP growth regressions, the foreign firm entry rate has a positive and significant average effect on subsequent patenting at the US patent office by incumbents listed on the London Stock Exchange, and this holds up to controlling for other factors, changing the model specification and, most importantly, controlling for the endogeneity of entry. As in column (3) of Table 1, the set of policy instruments is jointly significant in the first stage entry regression in column (3), Table 2. The residual from this first stage regression, when used as control function in the second stage regression, has a significant, negative coefficient indicating a negative bias in the non-instrumented entry coefficient and this is robust to several tested changes of the model specification or the instrument set.³⁶

The estimated effects of other factors are similar to our results for TFP growth models, and consistent with other findings in the literature. We again find a positive and significant coefficient for the distance to the industry-specific frontier. The inverted U-relationship we observe for competition and patent counts is in line with Aghion et al. (2005a). When controlling for import penetration, we find positive, but weak effects, as in Blundell et al. (1999) or Disney et al. (2003b).

³⁶When we change the set of instruments, as explained in subsection 5.1, we find significant, positive entry effects in all four model variants with reduced instrument sets. The respective instrument sets are jointly significant in the first stage and the second stage entry coefficients (*standard errors*) vary between 26.542 (15.877) and 45.956 (13.473).

In column (4) we explore the heterogeneity of foreign firm entry effects on subsequent incumbent innovation activity along the industry- and time-varying distance to the industry-specific frontier. As in TFP growth models, we find a negative and significant interaction term and positive and significant coefficients of the linear entry and distance to frontier terms. Thus, the positive effect of the linear entry term gets increasingly counteracted by the negative interaction effect the farther away the industry is from the technological frontier. This pattern provides support for the first empirical implication in section 2.

When we control for endogeneity of actual foreign firm entry and distance to frontier in column (5) of Table 2 we estimate first stage regressions for the linear entry term, the linear distance to frontier term and their interaction. The χ^2 -test results in the lower part of Table 2 show that the set of policy and US instruments we use has explanatory power in all three first stage regressions.³⁷ Joint exogeneity of all instrumented terms is rejected in the second stage regression. The pattern of our estimates remains robust to several tested changes of the model specification and the set of instruments.³⁸

The economic magnitude of the estimated effects also varies in a similar way along the sample distance to frontier distribution, as in the corresponding TFP growth model. In industries at median distance an increase of the foreign firm entry rate by one standard deviation (0.4 percent) raises the number of patents that incumbents take out subsequently by 6 percent, i.e. from the mean patent number of 8.1 to 8.6. In industries far from the frontier (90%-percentile) the subsequent patent number is reduced to 7.3 patents and close to the frontier (10%-percentile) it increases to 11.0 patents. The latter increase is equivalent to about 12 percent of the patent count standard deviation in the sample (24.1 patents) and,

³⁷We use as measures of the production and technology structure in US industries: the ratios of capital over labor and of skilled over all workers in 4-digit US industries as well as research and development intensities in 2-digit US industries. In addition we use all seven interaction terms between the US-related and policy instruments that turned out to be significant in the distance-related first stage regression.

³⁸Most important, we vary the set of instruments as for the TFP growth model in column (5), Table 1. The respective reduced instrument sets have explanatory power on the first stage and the two second stage entry-related coefficients are always jointly significant at the 2%-significance level. The linear entry coefficient takes values between 37.159 (*12.558*) and 73.645 (*40.757*), the linear distance term between 1.744 (*0.356*) and 3.296 (*0.746*) and the interaction coefficient between -109.856 (*51.515*) and -233.974 (*168.939*).

thus, the findings are reasonable.

Altogether, the patent count results suggest that a major driving force of the entry effects in our TFP growth estimations is incumbent innovation, not just imitation or reallocation.

5.3 Robustness

So far, we have presented empirical results that support the finding in Figure 1 and the theoretical interpretation put forward in Section 2. We used data on productivity growth and patenting of incumbents coming from different sources and showed robustness of the results to several changes of the model specification and instrumentation strategy. In this section we explore the robustness of our results in three other directions. First, we consider potential influences of measurement error. Secondly, we relax the key theoretical assumption that foreign firms always enter at the technological frontier and investigate effects of the domestic firm entry rate in that context. Third, we argue why the two most likely alternative interpretations based on knowledge spillovers do not fully explain our empirical findings.

5.3.1 Measurement issues

There are three forms of measurement error that concern us here - (i) measurement of dependent variables, (ii) measurement of the distance to the frontier, (iii) the consequences of using an unbalanced panel. We consider these in turn.

The standard factor share approach we use here to calculate TFP growth instead of estimating it has the advantage of involving the use of a superlative index building on a flexible translog production function. A usual concern, however, is that it relies on the assumption of perfect competition in factor and product markets. In case of imperfectly competitive product markets the level of TFP will systematically be overstated,³⁹ and if the impact of reducing entry barriers is accompanied by increasing competition, this would imply underestimating TFP growth. Thus, it is important to consider whether our results are robust to relaxing this assumption. We calculate an alternative measure of TFP growth

³⁹See, inter alia, Klette and Griliches (1996).

that takes imperfect competition into account (see Appendix B). When using the alternative measure we again obtain positive and significant coefficients for entry and the distance to frontier and a negative and significant coefficient for the interaction term. Using labor productivity growth also gives similar results.⁴⁰

Our second concern is with measurement of the distance to the frontier. In section 4.3 we introduce an index that relates labor productivity in 4-digit UK industries to labor productivity in corresponding 4-digit US industries as our preferred measure because it is not affected by capital stock measurement in the two relevant data bases. However, the results remain robust when using a relative TFP index that is also measured on the 4-digit industry level in columns (1) and (4) of Table 3. In addition to varying the index, we deviate from our preferred specification here: we interact entry with two dummies respectively indicating industries near or further behind the frontier, use as well the linear continuous distance to frontier term, and instrument all three terms. We find that both TFP growth as well as patent count regressions support the conjecture that entry threat spurs incumbents to invest in innovation most in industries near the technological frontier.

[Table 3 here]

Finally, we want to clarify that our results do not depend on poor performing incumbents that are driven out of the market by entrants and the subsequent reallocation of resources. We eliminate establishments and firms that drop out of our panels and show the respective TFP growth estimation in column (3) and the patent count estimation in column (6) of Table 3. The results are found to hold as well for these subsamples.

⁴⁰Using the alternative TFP growth measure leads to a coefficient (*standard error*) of -6.771 (2.872) for the interaction, 4.175 (0.422) for the linear entry and 0.088 (0.043) for the distance terms. Using labor productivity gives as estimates for the interaction, linear entry and distance terms: -8.308 (3.923), 2.381 (0.898), 0.289 (0.124). In both models the set of instruments is jointly significant on the first stage and overidentification tests do not reject.

5.3.2 Entry behind the technological frontier

In the empirical analysis above we focused entirely on foreign firm entry. Since foreign entry is from firms that operate internationally, and are more likely to produce at the technological frontier than other entrants in the UK, this accords well with considering technologically advanced entry in our theory section 2, where we assumed that entry takes place at the *new* frontier \bar{A}_t .

Alternatively, we can explore the case where entrants have productivity \bar{A}_{t-1} instead of \bar{A}_t using our theoretical framework. This case leads to the main conclusion that increasing the threat of entry encourages innovation and productivity growth in sectors that are at intermediate distance from the frontier; it discourages innovation in sectors that are far below the frontier; and it has little effect on innovation in sectors close to the frontier. In the case where entrants have productivity \bar{A}_{t-2} or are even further behind the frontier, no effects on innovation and productivity growth are to be expected.⁴¹

This prediction can explain the empirical results we find when exploring the effects of the domestic firm entry rate on subsequent incumbent TFP growth or patenting. Coefficient estimates for domestic entry terms always turn out to be insignificant in our models. See, for example, columns (2) and (5) in Table 3 and note that the coefficients of the foreign firm entry terms remain very similar to those in columns (5) of Tables 1 and 2. The insignificant coefficients for domestic entry terms are in line with the following findings from the literature on firm entry and new firm performance:⁴² The average domestic entrant is likely to struggle with survival during its initial period after market entry, is occupied with learning about its own productivity and market conditions and is usually very small compared to foreign entrants or incumbents in the same industry.⁴³ Among the small number of

⁴¹No entry would then be observed in the theoretical model since entry is optimal only when the entrant can take away market shares from the incumbent.

⁴²See, for example, Caves (1998), Dunne et al. (1988), Disney et al. (2003a) and Geroski (1995).

⁴³According to our ARD data, for example, the average plant size of domestic entrants is about 10 times smaller than that of foreign entrants in their industry and about 7 times smaller than that of incumbent plants that are at least 5 years old.

innovative domestic entrants are many that are initially hampered by financial constraints and immaturity of their technologies such that they are unlikely to challenge incumbents during their first years after market entry. Thus, aggregate domestic firm entry rates that do not exploit detailed firm information to separate between different types of domestic entrants pick up entry behind the technological frontier and insignificant effects on subsequent incumbent performance are reasonable.

5.3.3 Resource reallocation and knowledge spillovers

Our analysis so far contributes to a better understanding of the heterogeneity of entry effects on incumbent innovation and productivity growth across different industries. There are, however, other mechanisms whereby entry induces economic growth, that are not explored in this paper. The most important one is reallocation of productive inputs and outputs. High productivity entrants may induce the replacement of low productivity firms and thus increase productivity measured on an aggregated level. Empirical support for the importance of this mechanism is provided by Olley and Pakes (1996), Pavcnik (2002) and others. The dynamic industry model with heterogeneous firms by Melitz (2003) provides a theoretical analysis of reallocation effects triggered by opening up industries to international trade. In contrast to what we do, within-firm productivity is assumed to be constant in that paper and innovation incentives of incumbent firms are not considered. Bernard et al. (2003) consider reallocation of resources, plant turnover and measured productivity changes of incumbents caused by changing prices or by mark-up changes in an imperfect competition framework. They do not analyze effects of policy changes on within-firm incentives of incumbents, especially not heterogeneous within-firm reactions. While we do not consider the within-industry reallocation effects these papers focus on we investigate in detail how entry effects within-firm changes of innovation incentives and productivity growth, and does so differently in industries at different distance to the industry-specific technological frontier.

Finally, we want to discuss the extent to which alternative theoretical explanations are also consistent with the pattern of empirical results reported above. Potential candidates

are theories that focus on the role of knowledge spillovers instead of innovation incentives. Consider the widely established idea that firms and sectors further from the frontier should benefit most from knowledge spillovers, since the scope for learning is highest there.⁴⁴ This suggests positive coefficients on the linear distance to frontier terms, as well as on the interactions with entry. We find, however, a different pattern, namely negative interaction effects and positive level effects of the distance to frontier measure (see sections 5.1 and 5.2 and tables 1 to 3).

Our theoretical model generates predictions that are in line with both our empirical results. In section 2 we established the prediction of a negative interaction effect - innovation and productivity growth of incumbents in sectors close to the technological frontier react more positively to entry threat than in sectors further below the frontier. Now we show that if there is no threat of entry then the expected incumbent performance in a sector would be greater the further the sector is from the frontier (i.e. the level effect of the distance to the frontier would be positive). Assume for a moment that $p_1 = p_2 = 0$. Then the innovation rates in the different types of sectors become:

$$z_1 = (\delta/c) (\gamma - 1) < z_2 = (\delta/c) \gamma < 1$$

from which we obtain:⁴⁵

$$g_1 = z_1 (\gamma - 1) < g_2 = z_2 (\gamma - 1) < g_3 = (\gamma - 1).$$

Such a positive effect of the initial distance to frontier on expected productivity growth is to be expected in any model where sectors converge to the same expected growth rate.⁴⁶

⁴⁴Griffith et al. (2004) find empirical support for such consequences of general spillovers looking across a panel of OECD industries and countries. Griffith et al. (2002) find similar evidence at the establishment level in the UK.

⁴⁵See footnote 13 for the derivation of g_3 .

⁴⁶In this particular model the economic reason for the result is twofold. First, expected growth in a sector three steps behind the frontier is higher than in a sector two steps behind because the former sector upgrades with probability one. Second, when there is no entry threat then a sector that is two steps behind is expected to grow faster than a sector just one step behind, because if the leader of the state-2 sector does not innovate then its rival, who is three steps behind the frontier, will catch up with him and the leader will earn no

Another idea prevalent in the existing literature on knowledge spillovers argues that firms in industries closer to the technological frontier have higher absorptive capacity and may benefit more from spillovers. If so, then firms in industries closer to the frontier should react stronger to general spillovers, as well as to knowledge transfers from entrants, than firms in industries farther behind the frontier. Our finding of negative and significant coefficients on the interaction terms is consistent with this. But the positive and significant coefficients for the linear distance to frontier terms are not in line with this explanation.

6 Conclusions

In this paper we investigate the substantial heterogeneity we see in the effects of entry on incumbent performance. We show first that the finding can be explained in the context of a simple multi-sector Schumpeterian growth model with entry. The main implication of the theoretical model is that a higher threat from technologically advanced entrants should encourage incumbent innovation in sectors that are initially close to the technological frontier (this we refer to as the “escape-entry effect”), whereas it may discourage incumbent innovation in sectors that are initially further behind the frontier (this we call the “discouragement effect” of entry). The intuition for these two effects is quite simple. In the former case, incumbent firms that are initially close to the frontier know they can escape entry by innovating; therefore a higher threat of entry will result in more intensive innovation activities aimed at escaping that threat. In the latter case, incumbents that are further behind the frontier have no hope to win against an entrant.

In the second part of the paper, we estimate the effects of entry allowing for effect heterogeneity. We use panel data from two entirely different sources - one containing information on incumbent TFP growth at the establishment level, the other containing information on patenting behavior of stock market listed firms. In both cases we control for confounding

profits, whereas if the leader in a state-1 sector fails to innovate it will still remain one step ahead of its rival and hence will still earn positive profits; accordingly, the escape competition effect will give the leader in a state-2 sector a greater incentive to innovate than the leader of a state-1 sector.

factors and for endogeneity of our main measure for technologically advanced entry, the foreign firm entry rate. We exploit exogenous variation across industries and time coming from product market interventions in the UK, including the introduction of the EU Single Market Program, decisions by the competition authorities and (de)regulations in the form of privatization decisions. Given our focus on heterogeneity of entry effects along the distance to frontier we also consider the endogeneity of distance measures and use US production and technology information as additional instruments. Our empirical analysis provides robust evidence and vindicates the theoretical implications of our growth model with entry. Most important, technologically advanced entry by foreign firms has a positive effect on innovation in sectors initially close to the frontier, but not on innovation in sectors initially further behind the frontier, and the effect of entry on productivity growth interacts negatively with the distance to frontier.

The results of our theoretical and empirical analysis can be linked to the policy debates on market (de)regulation, competition policy, large scale privatization, and trade liberalization. The main implication is that policies aiming at decreasing or removing entry barriers alone may not be sufficient to foster growth of incumbent firms in all sectors of an economy, even if such policies are found to be growth-enhancing on average. This, in turn, may suggest the introduction of complementary policies that facilitate, as well as the abolition of regulations that slow down, the reallocation of factors and resources towards sectors responding more positively to higher entry threat.

A Theory appendix

A.1 Endogenizing entry:

Suppose that in an industry where the current leader is a type- j firm, entrants at time t need to pay the following entry fee to get an entry opportunity:

$$F_{jt} = \lambda \bar{A}_t + \eta(\bar{A}_t - \bar{A}_{t-j}),$$

where $j \in \{1, 2, 3\}$ and λ is random and uniformly distributed between 0 and Λ . The term in η reflects the additional cost that may arise for an entrant that brings up to frontier level a sector that was initially further below that frontier. In particular a high, positive η will tend to make the equilibrium probability of entry into an industry a decreasing function of the industry's initial distance to frontier, whereas the opposite will hold if η is small or equal to zero. Our main predictions turn out to be independent of whether η is high or low.

The probability of entry in a type- j sector is equal to the probability that the potential entrant pays the cost of entry, which in turn is the probability that the entrant's expected profit is greater than the entry fee F_{jt} .

In a type-2 or type-3 sector, where the expected profit of an entrant is $\delta \bar{A}_t$:

$$p_j = \text{pr}(\delta \bar{A}_t > F_{jt}) = \frac{\delta - \eta(1 - 1/\gamma^j)}{\Lambda}, \quad j \in \{2, 3\}. \quad (10)$$

In a type-1 sector, the expected profit of an entrant is $\delta \bar{A}_t(1 - z_1)$, where z_1 denotes the probability that a type-1 incumbent leader innovates. In the main text we showed that this innovation probability itself depends upon the entry threat p_1 , with

$$z_1 = \delta(p_1 + \gamma - 1)/c.$$

Thus, the probability p_1 must satisfy the fixed point equation:

$$p_1 = \text{pr}(\delta \bar{A}_t(1 - z_1) > F_{1t}) = \frac{\delta - \delta^2(\gamma - 1)/c - \eta(1 - 1/\gamma) - \delta^2 p_1/c}{\Lambda}, \quad (11)$$

or equivalently

$$p_1 = \frac{\delta - \delta^2(\gamma - 1)/c - \eta(1 - 1/\gamma)}{\Lambda + \delta^2/c}. \quad (12)$$

Therefore, all probabilities p_j are decreasing in the common entry cost parameter Λ , namely $p'_j(\Lambda) < 0$ with $j \in \{1, 2, 3\}$.

A.2 From entry threat to actual entry:

The actual rate of entry in state-2 sectors is

$$E_2 = p_2(\Lambda), \quad (13)$$

since potential entrants can never lose against a type-2 incumbent. Thus, entry threat and actual entry are the same, and therefore the comparative statics of innovation as a function of entry threat also leads to the unambiguous prediction of a negative correlation between innovation by type-2 incumbents and actual entry in state-2 sectors.

The actual entry rate in state-1 sectors is

$$E_1 = p_1(1 - z_1), \quad (14)$$

so that the relationship between entry threat and actual entry in state-1 sectors is a priori ambiguous: a higher entry threat induces more innovative activity by type-1 incumbents in order to prevent entry, thereby counteracting the positive direct effect of entry threat on actual entry. However, the overall effect of entry threat on actual entry is positive, i.e. the effect of the entry cost parameter Λ on actual entry is negative, when Λ is not too small relative to the profit rate δ and the inverse of the R&D cost parameter c . We have

$$\frac{\partial E_1}{\partial \Lambda} = \left(1 - \frac{1}{c}\delta(\gamma - 1) - 2\frac{1}{c}\delta p_1(\Lambda)\right)p_1'(\Lambda),$$

that is negative if and only if

$$p_1(\Lambda) < \frac{1 - \delta(\gamma - 1)/c}{2\delta/c}.$$

This holds if

$$\Lambda > \delta^2/c.$$

A.3 Steady-state distribution of sectors and average incumbent productivity growth

Here we derive the steady-state fractions of all sectors j and show that increased threat of entry has a positive effect on the average rate of productivity growth among active incumbent firms across all sectors of the economy for plausible values of the R&D cost parameter c , frontier growth rate γ , entry cost parameter Λ and the additional cost term η . The latter cost term arises for an entrant that brings up to frontier level a sector that was initially further below the frontier. Let q_j denote the steady-state fraction of sectors in state j and \bar{A}_{t-j} the productivity in such sectors at the beginning of period t . In steady state, the net flow of sectors into each technological state $j \in \{1, 2, 3\}$ must equal the net flow out of that

state. More formally, if p_j denotes the entry threat into a type- j sector, we have:

$$p_2 q_2 + p_3 q_3 = (1 - p_1)(1 - z_1) q_1; \quad (15)$$

$$(1 - p_1)(1 - z_1) q_1 = [p_2 + (1 - p_2)(1 - z_2)] q_2; \quad (16)$$

$$(1 - p_2)(1 - z_2) q_2 = p_3 q_3; \quad (17)$$

plus the normalization

$$q_1 + q_2 + q_3 = 1. \quad (18)$$

The left hand sides (right hand sides) of (15), (16) and (17) correspond to the net flows into (out of) states 1, 2 and 3, respectively. Only three of the above four equations are linearly independent, and thus can be used to solve for q_1, q_2, q_3 . Then, if g denotes the average productivity growth rate among active incumbent firms, we have:

$$g = q_1 g_1 + q_2 g_2 + q_3 g_3.$$

We want to know how this growth rate is impacted by an increase in the entry cost parameter Λ in the short run; that is, holding constant the probabilities q_i defining the distribution of initial technology gaps.

We can establish the following:

Proposition: For η, γ and Λ sufficiently small, if $\delta < c$ then:

$$\left. \frac{dg}{d\Lambda} \right|_{q=const} \equiv q_1 \frac{dg_1}{d\Lambda} + q_2 \frac{dg_2}{d\Lambda} + q_3 \frac{dg_3}{d\Lambda} < 0.$$

Proof: Since g_3 is independent of Λ , we have:

$$\left. \frac{dg}{d\Lambda} \right|_{q=const} = q_1 \frac{dg_1}{d\Lambda} + q_2 \frac{dg_2}{d\Lambda} = (\gamma - 1) \left(q_1 \frac{dz_1}{d\Lambda} + q_2 \frac{dz_2}{d\Lambda} \right),$$

where we have made use of equation (5) in the text. Let

$$u = \delta/c \quad \text{and} \quad \phi = \Lambda/\delta.$$

Now if we can prove the proposition for $\eta = 0$, by continuity it will also hold for η small. Thus, let us fix η at zero. Using (10) and (12) we can then reexpress the probabilities of entry as:

$$p_1(\phi) = \frac{1 - u(\gamma - 1)}{\phi + u} \quad \text{and} \quad p_2(\phi) = p_3(\phi) = 1/\phi. \quad (19)$$

We can use (19) to reexpress the equilibrium innovation rates z_1 and z_2 respectively as:

$$\left\{ \begin{array}{l} z_1(\phi) = u(p_1(\phi) + \gamma - 1) \\ z_2(\phi) = u(1 - p_2(\phi))\gamma \end{array} \right\} \quad (20)$$

Next, using the steady-state equations (15) \sim (18), we get:

$$\left\{ \begin{array}{l} q_1(\phi) = \frac{p_2(\phi)}{p_2(\phi) + (1-p_1(\phi))(1-z_1(\phi))} \\ q_2(\phi) = \frac{q_1(\phi)(1-p_1(\phi))(1-z_1(\phi))}{p_2(\phi) + (1-p_2(\phi))(1-z_2(\phi))} \end{array} \right\} \quad (21)$$

So, we have:

$$\begin{aligned} \frac{dg}{d\Lambda} \Big|_{q=const} &= (\gamma - 1) (q_1(\phi) \delta z'_1(\phi) + q_2(\phi) \delta z'_2(\phi)) \\ &\sim \left(z'_1(\phi) + \frac{q_2(\phi)}{q_1(\phi)} z'_2(\phi) \right) \\ &\sim \left(p'_1(\phi) - \frac{(1-p_1(\phi))(1-z_1(\phi))}{p_2(\phi) + (1-p_2(\phi))(1-z_2(\phi))} \gamma p'_2(\phi) \right) \\ &= \left(-\frac{1-u(\gamma-1)}{(\phi+u)^2} + \frac{(1-p_1(\phi))(1-z_1(\phi))}{p_2(\phi) + (1-p_2(\phi))(1-z_2(\phi))} \gamma \frac{1}{\phi^2} \right) \end{aligned}$$

Clearly ϕ and γ have a lower limit of unity. (If $\phi < 1$ then $p_2 = p_3 > 1$, which makes no sense.) As we approach the limiting case where $\phi = \gamma = 1$ then, from (19) \sim (21), we have:

$$p_1(\phi) \rightarrow \frac{1}{1+u}, \quad p_2(\phi) \rightarrow 1, \quad z_1(\phi) \rightarrow \frac{u}{1+u} \quad \text{and} \quad z_2(\phi) \rightarrow 0$$

Substituting these into the final expression above for $\frac{dg}{d\Lambda} \Big|_{q=const}$, we have in the limit:

$$\frac{dg}{d\Lambda} \Big|_{q=const} \sim \left(-\frac{1-u}{(1+u)^2} \right)$$

in which the right-hand side is negative when $\delta < c$ because then $u < 1$. ||

B Data appendix

B.1 Data sources

Plant and establishment level data for the manufacturing sector come from the UK Office for National Statistics (ONS). Its Annual Respondents Database (ARD) contains the micro data underlying the UK Annual Census of Production.⁴⁷ Annual data on industry classification, ownership and employment is available for the *whole population of British plants* and allows for the construction of entry measures.⁴⁸ Extensive additional data on inputs and outputs is available for a *random stratified sample of establishments* selected

⁴⁷For recent years, the database is named Annual Business Inquiry (ABI). See Barnes and Martin (2002), Griffith (1999) and Oulton (1997) for further information.

⁴⁸Before calculating entry measures we cleaned and checked the plant population data for 1973-1995, thereby reducing the number of observations by about 10 percent.

for a detailed annual survey.⁴⁹ The ARD survey is conducted under the 1947 Statistical Trade Act and survey response is mandatory. Establishments with more than 100 employees are all selected, as well as a stratified random sample of smaller units.⁵⁰ The plant and establishment data is supplemented with ownership information that is yearly updated from Dun & Bradstreet's "Who own's Whom". Owner nationality indicates for all plants and establishments of a firm the nationality of the largest shareholder controlling at least 20 percent of that firm. We weight observations by employment and the inverse of their sampling probability.

We restricted our sample to observations on incumbent establishments under domestic ownership that are (i) at least 5 years old *or* (ii) had at least once between 1986 and 1993 more than 100 employees.⁵¹ We excluded from the sample all establishments not yet producing or under public ownership, observations before 1987 and after 1993, trimmed the sample with respect to key variables,⁵² dropped establishments observed for less than three consecutive years and do not allow for reappearance of establishments. The resulting sample contains 23,802 observations on 4,947 domestic incumbent establishments. Descriptive statistics are provided in Table B.4.

Firm level data on patenting activity is taken from the NBER/Case Western Patent database that covers over two million patents granted by the US Patent Office since 1901. The patent data is linked to annual DataStream accounting data since 1968 for a sample of firms listed on the London Stock Exchange (LSE) in 1985.⁵³ All firms in the database are considered to be incumbent since firms listed at the LSE are typically reasonably old and large. For estimation purposes we purged the raw database from non-manufacturing firms and observations before 1987 and after 1993, trimmed the sample with respect to key variables,⁵⁴ and excluded firms with less than three consecutive observations considering accounting periods of less (more) than 300 (400) days as series breaks. This leaves us with

⁴⁹About 76 percent of all sampled establishments between 1980 and 1993 are single plants, all others represent groups of on average 1.6 plants operating in the same 4-digit industry and owned by the same firm.

⁵⁰The sample selected for the survey accounts for about 90 percent of annual total British manufacturing employment according to Oulton (1997).

⁵¹Empirical results were robust when experimenting with stricter definitions, for example, when imposing (i) *and* (ii).

⁵²We dropped observations with missing key variables (output, value added, intermediate inputs, employment, capital stock), observations where absolute growth in key variables was over 150 percent, and observations with extreme values below (above) the 1- (99-)percent percentiles of the productivity growth, entry rate or distance to frontier distributions.

⁵³The sample covers 415 firms listed at LSE in 1985 with names starting with A-L and all top 100 R&D spenders not already included. Subsidiaries of these firms were identified using "Who owns Whom" by Dun and Bradstreet in 1985 and all entities were matched by name to the NBER/Case Western Patent database. See Bloom and Van Reenen (2002) for further information.

⁵⁴We dropped observations with missing values of sales, capital and employment, observations where absolute growth of these key variables exceeded 150 percent, and observations with extreme values of the entry rate or distance to frontier distributions.

an estimation sample of 1,085 observations on 176 firms described in greater detail in Table B.4.

Industry level data on US 4-digit industries come from the NBER manufacturing productivity (MP) database and for UK industries it is aggregated from the ARD database.⁵⁵ When calculating the distance to frontier measures for the productivity growth (patent count) models we matched UK 4-digit (3-digit) industries to the corresponding US 4-digit (3-digit) industries. For the matching we used the US SIC 1987 and the UK SIC 1980 industry code.⁵⁶ Further 2-digit industry level data on import penetration in UK and US R&D intensity are taken from the OECD STAN database.

B.2 Definitions of variables

Productivity growth: When calculating TFP growth we apply a standard factor share approach, use a superlative index derived from a flexible translog specification of the production technology (Caves et al. 1982a, b), and disaggregated ARD survey data on establishment output and inputs:

$$\Delta TFP_{it} = \Delta \ln Y_{it} - \sum_{z=1}^Z \tilde{\alpha}_{it}^z \Delta \ln x_{it}^z, \quad (22)$$

where Y denotes output, Z the number of factors of production, and x_{it}^z the quantity used of factor z in establishment i at time t . We consider four factors of production in Z : skilled labor (administratives, technical and clerical workers), unskilled labor (operatives), the stock of physical capital, and intermediate inputs.

Factor shares $\tilde{\alpha}_{it}^z$ are defined as $\tilde{\alpha}_{it}^z = (\alpha_{it}^z + \alpha_{it-1}^z)/2$ with α_{it}^z denoting the cost of factor z relative to total output value in establishment i at time t . Since observed factor shares α_{it}^z can be noisy and may exceed one we apply a smoothing procedure proposed by Harrigan (1997). Assuming a translog production technology, constant returns to scale (CRS), and standard market-clearing conditions, α_{it}^z can be expressed as follows:

$$\alpha_{it}^z = \psi_i + \varphi_{jt} + \sum_{z=2}^Z \omega_j^z \ln \left(\frac{x_{it}^z}{x_{it}^1} \right), \quad (23)$$

where ψ_i is a establishment-specific constant, φ_{jt} an industry-time-specific constant and where we normalize relative to production factor 1 to impose CRS.⁵⁷ If observed factor shares deviate from the left-hand side of this equation by an i.i.d. measurement error term,

⁵⁵See Bartelsman and Gray (1996) and Griffith (1999) for variable definitions in both databases.

⁵⁶Of all 205 4-digit industries in the ARD database 146 could be linked exclusively to one or several US 4-digit industries. 50 of the remaining industries could be successfully linked to US industries after having formed pairs and three larger groups of 4-digit industries. Nine UK industries could not be linked to an industry in the US manufacturing sector.

⁵⁷See Caves et al. (1982b) and Harrigan (1997).

then its parameters can be estimated by running separate fixed effects panel data regressions for each 4-digit industry j . The fitted values from (23) are then used as factor shares in the calculation of (22).

For our main TFP growth measure we impose constant returns to scale ($\sum_z \tilde{\alpha}_{it}^z = 1$). Alternatively, we follow Klette (1999) and use estimated price markups above costs to calculate a second TFP growth measure that does not depend on the assumption of perfect product market competition.⁵⁸

Number of patents: The dependent variable in the patent count models is the annual number of patents a firm listed at the LSE took out at the U. S. Patent Office.

Import penetration: We calculate the ratio of the annual value of imports over domestic output using 2-digit industry level data from the OECD STAN database.

Competition: For the productivity growth (patent count) models we use a 4-digit (3-digit) industry level competition index that is defined as 1 minus a market share-weighted average of the Lerner index across all establishments in the industry. The measure takes values between 0 and 1 and a value of 1 indicates perfect competition. The establishment-specific Lerner index is proxied by annual output minus labor, intermediate good and capital costs divided by output using ARD data.⁵⁹

Pre-sample patent variable: Pre-sample patent information for firms listed at LSE is used to construct a measure of the firm-specific *patent stock* built up between 1968 and the beginning of the first year the firm is in our estimation sample, i.e. 1987 in most cases. We apply the perpetual inventory method and calculate the stock measure as the sum of all pre-sample patents depreciated to the end of the pre-sample period using an annual knowledge depreciation rate of 30 percent.⁶⁰ In addition to the stock measure, we constructed an *indicator of pre-sample patenting activity* equal to one if the firm ever patented in the pre-sample period.

For the definition of *entry* and *distance to frontier measures* see section 4 in the main text.

[Tables B.1-B.4 here]

⁵⁸Empirical results when using this measure and results when using a standard labor productivity measure are reported in sub-section 5.3.1.

⁵⁹Experimenting with an unweighted average or different weights had only negligible effects on the estimated effects of entry, distance to frontier and interaction terms. Using a market share measure instead of a rent-based competition measure also gave similar results.

⁶⁰We found our empirical results to be insensitive to the chosen depreciation rate when experimenting with other rates between 15 and 45 percent.

Figure 1: Entry effects near and far from the technological frontier

Notes: The figure plots spline estimates of the relation between the foreign firm entry rate and subsequent TFP growth of domestic incumbent establishments in UK 4-digit industries, 1987 to 1993. Each dot represents the average TFP growth estimate for establishments in one industry-year cell. Three spline points are chosen such that all establishment observations in industry-year cells with non-zero entry are grouped into four equally sized classes. The distance to technological frontier is a relative labor productivity measure relating 4-digit US to UK industries. The top (blue) curve is for establishments in industry-year cells near the technological frontier, i.e. less or equally distant to the frontier as the sample median of the distance. The bottom (red) curve is for establishments further behind the technological frontier, i.e. more distant to the frontier than the sample median.

Table B.1: Product market policy interventions

EU Single Market Program (SMP)	Year	
The implementation of the EU SMP began in 1988 and 41 3-digit industries were ex ante expected to be strongly or moderately affected by it. The aims of the SMP were to bring down EU internal barriers to the free movement of goods, services, capital and labor by interventions like harmonizing product standards, indirect taxes and border controls, removing national requirements and other non-tariff barriers that enable firms to segment markets and limit competition, restricting public sector discrimination in favor of its own firms, and reducing capital as well as labor costs by permitting free flow across countries. ¹	1988	
Monopoly and merger cases	Year	Industry code (SIC 80)
The UK Competition Authority has responsibility for undertaking case-by-case investigations of potential mergers or potential monopoly situations in order to determine whether the merger or actions of firms in the industry are, or can be expected, to operate against the public interest by distorting competition, preventing entry, increasing prices or reducing consumers' choice. Where the Commissioners conclude that this is the case they can recommend remedial interventions such as prohibitions or divestments. We use information on cases where remedial actions were recommended and undertaken. ²		
Opium derivatives	1987	2570
Advertising in rambling magazines	1987	4751
Roof trusses and connector plates	1988	3204
Medical and surgical equipment	1988	3720
Beer and brewing industry	1988, 1990, 1992	4270
Defense equipment, electronics industry, telecommunications	1989	3433
Sewing thread and textile industry	1989	4321
Tires	1989	4811
Fertilizers	1990	2513
Razors and shaving equipment	1990	3162
Sugar	1991	4200
Carbonated drinks and soft drinks	1990	4283
Matches, cigarette lighters, smokers requisites	1991	2565
Wool, wool scouring, textile industry	1991	4310
Shoe polish	1992	2599
Dairy products and milk	1992	4130
Cross media promotion of publications	1992	4753
Animal waste, Rendering, Meat	1992	4126

¹ See the European Commission's White Paper (1985) and Mayes and Hart (1994) for further details on EU SMP. The list of 41 3-digit industries that were ex ante expected to be affected by the introduction of the EU Single Market can be found in Mayes and Hart (1994, p.53).

² See <http://www.competition-commission.gov.uk/> for published case reports. Davies et al. (1999) and Clarke et al. (1998) provide further analyses of these cases.

Privatization cases	Year	Industry code
The Thatcher government embarked on a large scale privatization program in the early 1980s which led to the sale of a substantial portion of government owned assets. In most cases, these privatization decisions resulted in opening up these and related markets to entry by new firms. ³		
Ordnance, small arms and ammunition: Royal Ordnance	1987	3290
Car parts: Unipart	1987	3530
Aerospace equipment manufacturing: Rolls Royce	1987	3640
Motor vehicles and engines: Leyland Bus, Leyland Truck, Freight Rover, Rover Group.	1987, 1988	3510
Shipbuilding: British Shipbuilders	1987, 1988, 1989	3610
Iron and steel industry: British Steel	1988	2210
Telecommunication equipment: British Telecom	1991	3441

Table B.2: Large 4-digit industries by distance to technological frontier

SIC 80 code	Industry description	US-UK relative labor productivity, 1984-1986
Large industries close to the frontier (\leq median distance to frontier)		
4310	woolen and worsted industry	0.084
4671	wooden and upholstered furniture	0.049
4510	Footwear	0.111
4725	packaging products of boards	0.118
4751	printing and publishing of newspapers	0.214
4536	woman's and girl's light outerwear	0.290
4363	hosiery and other weft knitted goods and fabrics	0.316
3443	radio and electronic capital goods	0.362
3284	refrigerating, heating and ventilating equipment	0.414
2489	ceramic goods	0.426
Large industries further behind the frontier ($>$ median distance to frontier)		
3420	basic electrical equipment	0.517
3640	aerospace equipment manufacturing and repairing	0.519
2570	pharmaceutical products	0.585
4196	bread and flour confectionery	0.664
4197	biscuits and crisp-bread	0.664
2551	Paints, varnishes and painters' filings	0.691
4270	brewing and malting	0.779
4122	bacon curing and meat processing	0.893
3460	domestic-type electric appliances	0.894
3530	motor vehicle parts	0.945

Notes: The industries listed here are the largest UK 4-digit industries in the group of industries close to the technological frontier and further behind the frontier. Industry size is measured by employment and the distance by labor productivity in 4-digit US relative to UK industries between 1984 and 1986. Calculations are based on data for all 1235 industry-year cells in the estimation sample for productivity growth models.
