**ABSTRACT**

Using *RXTE* and *ASCA* data, we investigate the roles played by occultation and absorption in the X-ray spin pulse profile of the intermediate polar PQ Gem. From the X-ray light curves and phase-resolved spectroscopy, we find that the intensity variations are the result of a combination of varying degrees of absorption and the accretion regions rotating behind the visible face of the white dwarf. These occultation and absorption effects are consistent with those expected from the accretion structures calculated from optical polarization data. We can reproduce the changes in absorber covering fraction either from geometrical effects, or by considering that the material in the leading edge of the accretion curtain is more finely fragmented than in other parts of the curtain. We determine a white dwarf mass of $\sim$1.2 using the *RXTE* data.

**Key words:** accretion, accretion discs – binaries: close – stars: individual: PQ Gem – stars: magnetic fields – novae, cataclysmic variables – X-rays: stars.

## 1 INTRODUCTION

Magnetic cataclysmic variables (MCVs) can be split into two groups: those in which the magnetic field of the accreting white dwarf is strong enough ($\gtrsim$10 MG) to synchronize its spin period with that of the binary orbital period (the polars) and those with a magnetic field insufficiently strong to achieve this synchronization (the intermediate polars, IPs). The MCV PQ Gem is unusual in that it exhibits characteristics of both groups: it shows a strong soft X-ray component ($kT \sim 50$ eV, Duck et al. 1994), it is polarized in the optical/infrared (IR) wavebands (Potter et al. 1997; Piirola, Hakala & Coyne 1993) and has an estimated magnetic field strength of $\sim$8–21 MG (Väth, Chanmugam & Frank 1996; Potter et al. 1997; Piirola et al. 1993) – all of which are characteristics of polars. On the other hand, it shows a spin period of 833.4 s (Mason 1997) and an orbital period of 5.19 h (Hellier, Ramseyer & Jablonski 1994), which are typical of IPs. PQ Gem can therefore be thought of as the first true 'intermediate' polar (Rosen, Mittaz & Hakala 1993).

PQ Gem has been observed using several X-ray satellites (*ROSAT*, *Ginga*, *ASCA* and *RXTE*). The X-ray light curves show a prominent modulation on the spin period, in particular, a pronounced dip in the light curve, which is thought to be caused by an accretion stream obscuring the main emission region on the surface of the white dwarf. Mason (1997) made a study of the then available X-ray data to determine an accurate ephemeris for PQ Gem based on timings of the dip. However, a detailed study of the spectral information contained in the *ASCA* data was not undertaken.

*E-mail: chj@mssl.ucl.ac.uk

This paper is primarily targeted at reaching a greater understanding of the interplay between the emission sites and absorption that produces the observed modulation of the X-ray light curves. This is achieved through analysis of the *ASCA* spectral data with supporting evidence from the hard X-ray *RXTE* light curves. The mass of the white dwarf is calculated from the *RXTE* spectral data using the stratified accretion column model of Cropper et al. (1999, hereafter CWRK). A fuller report is available in James (2001).

## 2 OBSERVATIONS AND DATA REDUCTION

### 2.1 *ASCA*

*ASCA* was launched in 1993 carrying two X-ray charge-coupled device (CCD) cameras (SIS) and two imaging gas scintillation proportional counters (GIS), and operated until 2000 (Tanaka, Inoue & Holt 1994). The SIS detectors covered the energy range 0.4–10 keV, with an energy resolution of 2 per cent at 5.9 keV. The GIS detectors had an energy range of 0.7–10 keV, with an energy resolution of 8 per cent at 5.9 keV. Above 8 keV the GIS had a greater effective area than the SIS.

Details of the observations of PQ Gem are given in Table 1. The SIS detectors were configured to faint data mode 2-CCD (high bit rate) and 1-CCD (medium bit rate) clocking modes and the GIS detectors were configured to PH-mode. It is not possible to merge data from the different types of detector or from different SIS clocking modes without loss of information. Hence the end product of the data selection and reduction was several data files with effective exposures ranging from 24.7 to 36.9 ks.

The data selection and reduction were carried out following recommended procedures (for details see James 2001). The

**Table 1.** Details of the *ASCA* observations and data used in the analysis for this paper.

| Date | Instrument | Bit rate | Integration time (s) | Average (count $s^{-1}$) |
|---|---|---|---|---|
| 1994 April 11 | SIS0 | High | 26 786 | 0.35 |
| | | Medium | 36 910 | 0.38 |
| | SIS1 | High | 24 732 | 0.29 |
| | | Medium | 34 734 | 0.31 |
| | GIS2 | High | 27 771 | 0.25 |

observation was made early in the *ASCA* mission prior to the onset of the degradation of the CCDs caused by radiation damage (Yaqoob et al. 2000). Hence, the background spectra for SIS were created using the appropriate blank-sky event lists (available as part of *ASCA* calibration data) together with the data selection criteria corresponding to each event list. Background spectra for GIS were created in a similar fashion using blank-sky event lists. Background light curves were created from a source-free region of the same observation and subjected to the same screening criteria as for the source light curves.

### 2.2 *RXTE*

The *Rossi X-ray Timing Explorer* (*RXTE*) was launched on 1995 December 30. A review of the available instrumentation and the scientific results of the first years are given in Swank (1998).

Details of the *RXTE* observations of PQ Gem used in this paper are given in Table 2. Only the top xenon layer was selected from the five PCA instruments, so as to improve the signal-to-noise ratio. The standard *RXTE* procedures were used to select data (for details see James 2001). The background was modelled using the latest faint background model appropriate for the epoch of the observation, i.e. files faintl7_e03v03.mdl and faint 240_e03$v$03.mdl.

## 3 LIGHT CURVES

The quadratic spin ephemeris of Mason (1997) was used throughout the analysis of the light curves which were heliocentrically corrected.

### 3.1 Period analysis

The variability in the *RXTE* and *ASCA* light curves was analysed using a standard discrete Fourier transform (DFT) code Deeming 1975; Kurtz 1985). The equation, $z_0 = -\ln[1-(1-p_0)^{1/N}]$ (Scargle 1982) was used to determine the power level, $z_0$, above which an amplitude peak would be spurious for a small fraction, $p_0$, of the time, where $N$ is the number of frequencies examined. A 90 per cent confidence ($p_0 = 0.1$) was used to determine the signal-to-noise ratio level above which the amplitude of a power peak was judged to be significant. The noise level of the periodogram was taken to be the mean of the amplitude spectrum after it had been pre-whitened with frequencies found to be significant (Table 3). The

**Table 2.** Details of the *RXTE* PCA observations and data used in the analysis for this paper.

| Date | Instrument | Integration time (s) | Average (count $s^{-1}$) |
|---|---|---|---|
| 1997 January 27–30 | PCA | 51 216 | 13.9 |

**Table 3.** The details of the significant power peaks found from period analysis of *ASCA* SIS1 data and *RXTE* PCA data. The signal-to-noise ratio was taken as the amplitude of the power peak to the mean of the pre-whitened spectrum.

| Satellite | Instrument | Passband (keV) | Frequency (mHz) | Period (s) | S/N |
|---|---|---|---|---|---|
| *ASCA* | SIS1 | 0.7–10.0 | 1.199 81 (25) | 833.46 (17) | 8.0 |
| | | | 2.399 94 (32) | 416.678 (56) | 7.1 |
| | | | 3.600 19 (32) | 277.763 (25) | 6.6 |
| *RXTE* | PCA | 2.0–25.0 | 1.199 703 (81) | 833.540 (56) | 12.8 |

error in each such frequency was taken to be the standard deviation, $\sigma$, from a least-squares fitting.

The *ASCA* data showed three significant periods, 833.46, 416.678 and 277.763 s, which are consistent with the spin ephemeris of Mason (1997) and its first two harmonics. The *RXTE* data showed a significant period of 833.54 s. The spin period (833 s) is consistent with the spin-down rate predicted by the ephemeris of Mason (1997). The complete results are given in Table 3 for those signals identified as significant at the 90 per cent confidence level. The amplitude spectra, and window functions for *RXTE* and *ASCA* are shown in Fig. 1, along with the spectra pre-whitened with the frequencies of the significant power peaks and the expected positions of the orbital, beat, spin frequencies and spin harmonics. The residual power peaks in the pre-whitened *RXTE* periodogram are the third harmonic of the spin period (>68 per cent confidence level) and the first and second harmonics (<68 per cent confidence level).

Using an orbital period of 5.19 h Hellier et al. (1994) a beat period at 14.54 min may be expected. However, there is no evidence for a significant amplitude at the frequencies corresponding to the orbital or beat periods in either the *RXTE* or the *ASCA* data (Fig. 1). This indicates that the accreting material must go through a disc since all orbital information will then be lost.

### 3.2 *ASCA* light curves

Light curves of these data were first presented in Mason (1997) and also in James et al. (1998). They are presented here for completeness and comparison with those from *RXTE*. Light curves using data from the SIS0 detector for energy bands 0.7–1.0, 1.0–2.0, 2.0–4.0, 4.0–10.0 keV and from the total bandpass (0.7–10.0 keV) folded on the spin period are shown on the left-hand side of Fig. 2. The light curves were not folded on either the orbital or beat periods owing to the lack of amplitude peaks found at these frequencies in the power spectrum of the *ASCA* data (Section 3.1).

### 3.3 *RXTE* light curves

Light curves were extracted for the energy bands 2.0–4.0, 4.0–10.0, 8.0–25.0 keV and from the total bandpass, 2.0–25 keV, which were then folded on the spin period (right-hand side, Fig. 2). The first two energy bands can be directly compared with similar plots using the *ASCA* data.

### 3.4 Comparison between the *ASCA* and *RXTE* light curves

The *RXTE* PCA instrument overlaps the *ASCA* SIS instruments across the 2–10 keV energy band. Hence this energy band from both instruments was used to compare the light curve modulation of the two observations (Fig. 2). The light curves in these two bandpasses were found to be very similar, each with two maxima separated by a minimum at spin phase $\phi \sim 0.0$ (referred to as 'the dip', Mason

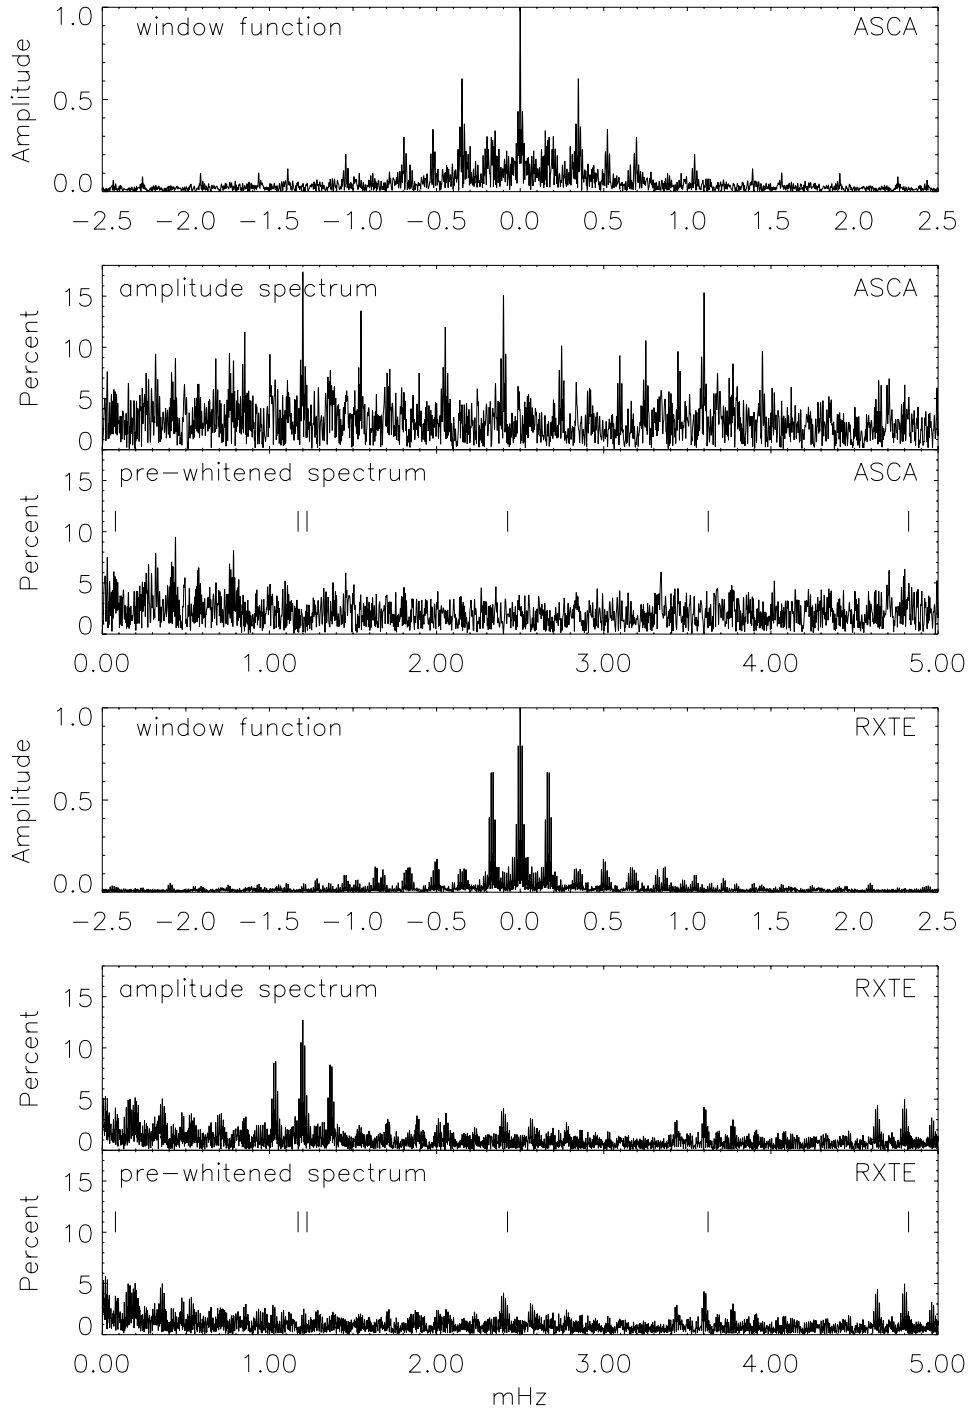

**Figure 1.** Periodograms for the *ASCA* 0.5–10.0 keV light curve (upper half) and *RXTE* 2.0–25.0 keV light curve (lower half) of PQ Gem. In each half the top plot shows the window function, in the middle plot, the amplitude spectrum and the bottom plot shows the spectrum pre-whitened with the frequencies of the significant peaks. The vertical bars (from left to right) mark the position of the orbital, beat and spin ($\omega$) frequencies plus the first, second and third harmonics of $\omega$, respectively. The relevant details are given in Section 3.1 and Table 3.

et al. 1992) and a second minimum at $\phi \sim 0.6$. In the 4.0–10.0 keV light curves the minima are relatively shallow in both the *ASCA* and the *RXTE* light curves, but the 2.0–4.0 keV light curves show well-defined 'dips' at $\phi = 0.0$, with a broader minimum at $\phi \sim 0.6$. There is some evidence that the amplitude of the variation in the *RXTE* folded light curve is less than that in the *ASCA* SIS data. The shape of 'the dip' in the 2.0–4.0 keV band is 'V'-shaped in *RXTE* compared with a more 'U'-shaped one in the *ASCA* light curve and its depth appears to be greater in the latter. This may be a result of a higher level of absorption at the earlier epoch of the *ASCA* observation.

### 3.5 *RXTE* hardness ratios

Plots of the 8.0–25.0 keV/2.0–8.0 keV and 8.0–25.0 keV/2.0–4.0 keV hardness over the spin period are shown in Fig. 3. The

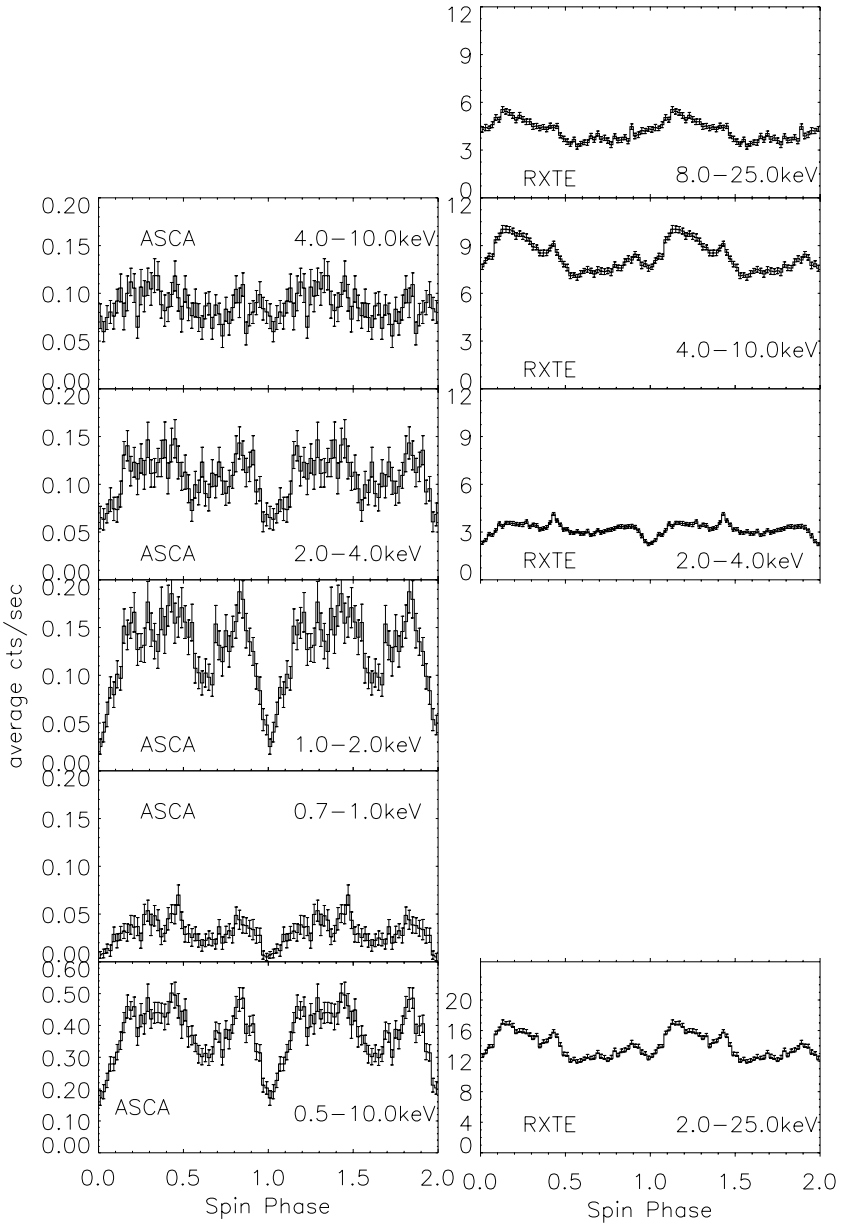

**Figure 2.** Background-subtracted light curves of PQ Gem using *ASCA* SIS0 and *RXTE* PCA data folded on the spin period. On the left-hand side are the *ASCA* light curves for energy bandwidths 4.0–10 keV (top), 2.0–4.0 keV (second from top), 1.0–2.0 keV (middle) and 0.7–1.0 keV (second from bottom) 0.5–10.0 keV (bottom). On the right-hand side are the *RXTE* light curves for energy bandwidths 8.0–25.0 keV (top), 4.0–10.0 keV (second to top), 2.0–4.0 keV (third to top), 2.0–25 keV (bottom).

lower limit of the 8.0–25.0 keV energy band was chosen so as to be well above the main absorption edges. A higher value of the ratio indicates those positions in the spin cycle that are more affected by absorption. These are consistent with the dip at $\phi = 0.0$ being caused by absorption.

## 4 SPECTRAL ANALYSIS

Because the energy resolution of the *RXTE* PCA (18 per cent at 6.0 keV) is much poorer than that of the *ASCA* SIS (2 per cent), and does not extend to lower energies, the spectral analysis was restricted to the *ASCA* data. During the spectral analysis the medium and high bit rate SIS data from both instruments and the GIS data were linked through the models and fitted simultaneously.

### 4.1 Integrated spectrum

The integrated spectrum was modelled using the MEKAL code for an optically thin emission model (Mewe, Kaastra & Liedahl 1995) for the hard X-ray spectrum and a blackbody model for the soft X-ray continuum. The temperature of the former was difficult to constrain, a problem that was similarly experienced by Duck et al. (1994) using *Ginga* data. Therefore, the temperature was fixed at 20 keV in line with the results from their analysis (we tried fixing the temperature at other values, but this did not have a significant effect on the results). The temperature of the blackbody component was not well constrained and therefore this spectral component was fixed at 55 eV in line with that found with *ROSAT* data (Duck et al. 1994) owing to its greater sensitivity to this spectral range. The fluorescent iron line

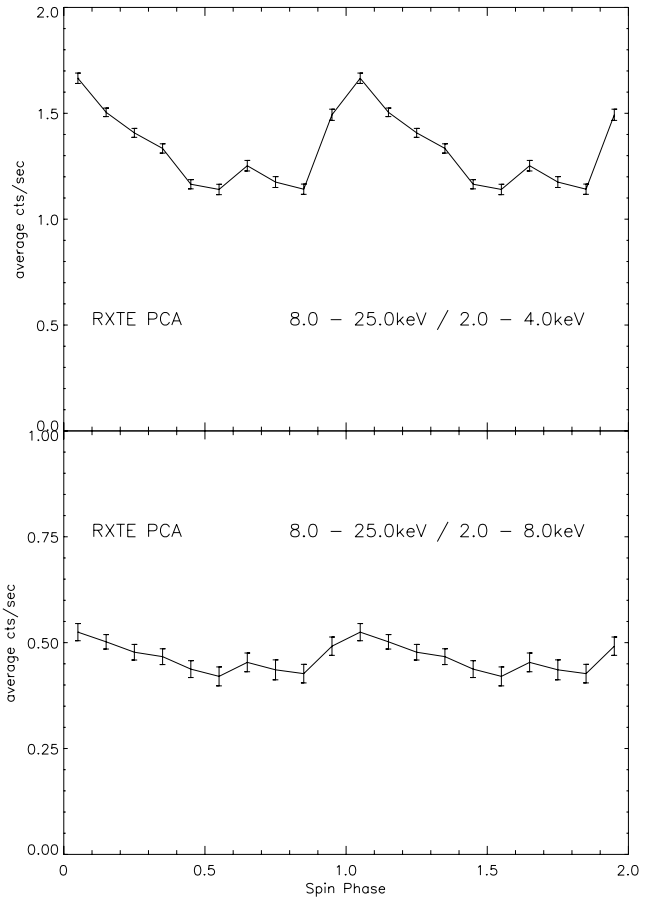

**Figure 3.** Plots of the 8.0–25.0 keV/2.0–8.0 keV (below) and 8.0–25.0 keV/2.0–4.0 keV (above) hardness ratios folded on the spin period. The errors are $1\sigma$.

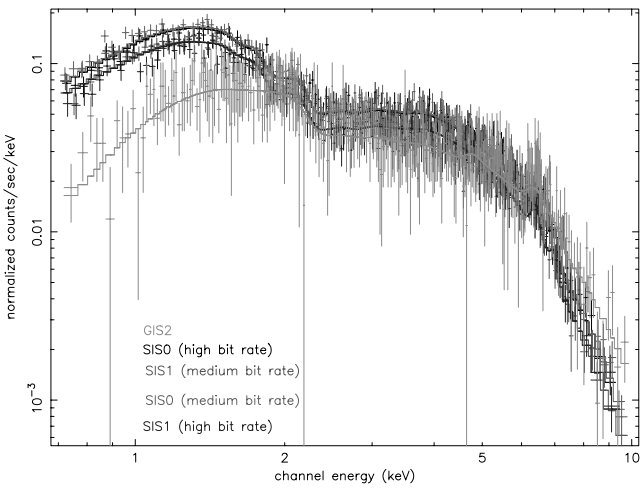

**Figure 4.** Integrated spectra of PQ Gem. Data from the medium and high bit rate data from the SIS1 and SIS0 instruments and the high bit rate data from the GIS2 instrument with the fitted model (Table 4).

at 6.4 keV was modelled using a Gaussian component, the width of which was fixed at 0.05 keV. A single homogeneous photoelectric absorber gave a poor fit ($\chi^2_\nu = 2.0$), therefore an inhomogeneous (partial covering) photoelectric absorber was added to the model. A good fit to the data was achieved in this way ($\chi^2_\nu = 1.07$). The values of those parameters allowed to vary during the fitting are given in Table 4 and the integrated spectra are plotted in Fig. 4.

### 4.2 Phase-resolved spectroscopy

Even though a good fit to the integrated spectrum was obtained, the results from the 8.0–25.0 keV/2.0–8.0 keV and 8.0–25.0 keV/2.0–4.0 keV hardness ratios using the *RXTE* PCA data indicate the possibility of variation in the absorption during the spin cycle (Fig. 3, Section 3.5). These two results imply that variability in both the absorption and the normalization of the hard X-rays over the spin cycle could be the cause of the observed modulation in the spin-folded light curves. In order to investigate this further we divided the spin period into 10 equal time bins and extracted spectra for each using data from both the SIS and GIS2 instruments. During all subsequent spectral fitting the medium and high bit rate data from both SIS and the GIS2 instruments were linked through the models and fitted simultaneously.

The reference model was derived from $0.4 \leqslant \phi < 0.5$, since this phase had the greatest number of counts. The model resembled that obtained from the integrated spectrum with the exception of the blackbody component, for which the temperature was significantly higher (best fit $= 83$ eV). In this more detailed analysis it was considered to be more appropriate to fix the temperature of the blackbody component of the other phase-resolved spectra at this value. The best-fitting model comprised three emission components: an optically thin plasma emission component with a temperature of 20 keV (fixed), a blackbody component with a temperature of 83 eV and a Gaussian at 6.4 keV to model the fluorescent Fe emission line (with a fixed width of 0.05 keV). Two photoelectric absorption components were required to model the attenuation of the X-rays: an inhomogeneous (partial covering) neutral absorber and a homogeneous neutral absorber. The latter had a best fit of $6.8 \times 10^{20}$ cm$^{-2}$: this component was fixed at this value in the other phase intervals. The metal abundance had a best fit of 0.34 solar – again this was fixed at other phase intervals. We now allowed the normalization of

**Table 4.** Results from a spectral analysis of the *ASCA* integrated spectrum of PQ Gem including the error range at 90 per cent confidence level. The optically thin plasma and blackbody temperatures were fixed at 20 keV and 55 eV, respectively. $N_{\rm H}(1)$ corresponds to the homogeneous absorber, whereas $N_{\rm H}(2)$ applies to the inhomogeneous (partial covering) absorber; the flux is not corrected for absorption. The model was fitted simultaneously to the medium and high bit rate data from the SIS1 and SIS0 instruments and the high bit rate data from the GIS2 instrument.

| $N_{\rm H}(1)$ $10^{22}$ cm$^{-2}$ | $N_{\rm H}(2)$ (fraction) $10^{22}$ cm$^{-2}$ | BB norm: $10^{-3}$ | MEKAL norm: $10^{-2}$ | Gaussian norm: $10^{-5}$ | Flux (observed) 2–10 keV $10^{-11}$ erg cm$^{-2}$ s$^{-1}$ | $\chi^2_\nu$ (dof) |
|---|---|---|---|---|---|---|
| $0.12^{+0.02}_{-0.03}$ | $8.3^{+0.9}_{-1.3}$ ($0.53^{+0.01}_{-0.02}$) | $2.0^{+2.3}_{-0.4}$ | $1.71^{+0.05}_{-0.06}$ | $4.9^{+1.3}_{-0.9}$ | 2.12 | 1.07 (1070) |

**Table 5.** The variable parameter values from spin-phase-resolved spectral analysis over 10 phase-bins. The reference model ($0.4 \leqslant \phi < 0.5$) was simultaneously fitted to the medium and high bit rate data from both of the SIS instruments and high bit rate data from the GIS2 instrument on the *ASCA* satellite. The normalization and absorption parameters only were varied from those of the reference model. The blackbody, bremssstrahlung normalizations and absorption include the error range at the 90 per cent confidence level. The blackbody, Mekal and Gaussian normalizations are standard for the relevant XSPEC models. Also included are the $\chi^2_\nu$ and observed flux (i.e. not corrected for absorption) for the 10 phases.

| 0.9–0.0 | $4.8^{+1.5}_{-1.1}$ | $0.58^{+0.03}_{-0.03}$ | $1.42^{+0.48}_{-0.55}$ | $1.87^{+0.16}_{-0.12}$ | $11.8^{+3.20}_{-5.24}$ | 2.2 | 0.95 (218) |

the X-ray emission and the partial covering absorption component to vary during the remaining nine phase bins of the *ASCA* data. We also allowed the normalization of the blackbody and the Fe fluorescent emission line to vary.

The resulting best-fitting parameter values from this analysis are shown in Table 5. The variations in the normalization of the optically thin plasma, the column density and the partial covering fraction are plotted in Fig. 5, together with the folded light curve for the 0.5–10.0 keV energy band of the *ASCA* data. It can be seen that the column density does not vary significantly over the whole spin cycle. The normalization parameter of the hard X-ray component shows a maximum over $0.2 \leqslant \phi < 0.4$, decreasing to a minimum at $\phi = 0.7$. The covering fraction of the partial absorber component shows a steady decline from its maximum value at $\phi = 0.0$ to a minimum value at $\phi = 0.5$. This pattern and phasing closely follows that of the *RXTE* 8.0–25.0 keV/2.0–8.0 keV hardness ratio, shown in Fig. 3.

Relating this back to the main features of the modulation of the light curve shows that the maximum countrate ($0.1 \leqslant \phi < 0.4$) is caused by a combination of increasing normalization coupled with a decreasing level of absorption. It would appear that an increase in the normalization factor is probably the main cause of the second maximum ($0.75 \leqslant \phi < 0.85$) of the light curve, but a contribution from a decrease in the covering fraction may also play a part. The secondary minimum ($0.55 \leqslant \phi < 0.75$) is mainly a result of a lower normalization factor. Finally, 'the dip' can be accounted for by the maximum value of the covering fraction, although, again, a contribution from a slight decrease in the normalization factor cannot be ruled out.

## 5 MASS OF THE WHITE DWARF

### 5.1 Procedure

In recent years much work has been done in determining the shock temperature in magnetic CVs (e.g. Fujimoto & Ishida 1997; Cropper, Ramsay & Wu 1998). One of the main goals of this work has been to estimate the mass of the white dwarf since these two parameters are closely linked. To estimate the mass of the white dwarf in PQ Gem we use the emission model of CWRK to fit data from the *RXTE* PCA detector (since it has an extended high-energy range – the temperature of the hard X-ray component was poorly constrained using the *ASCA* data because of the 10-keV upper limit). This model was developed to fit high-quality X-ray spectra appropriate to the conditions found in the accretion sites of MCVs. It is a more complex model than the generalized optical thin plasma code we used for phase-resolved spectroscopy.

The parameter, $\epsilon_{\rm s}$ (the ratio of the cyclotron to bremsstrahlung cooling at the shock), was fixed at 0.5 which, from fig. 1(b) of Wu, Chanmugam & Shaviv (1995) corresponds to a magnetic field strength of $\sim$15 MG (Piirola et al. 1993; Väth et al. 1996; Potter et al. 1997). We stratified the volume between the surface of the white dwarf and the shock front (Cropper et al. 1998) into 100 levels. The free parameters during the spectral fitting were the specific accretion rate in g cm$^{-2}$ s$^{-1}$ and the mass of the white dwarf. A viewing angle is also required to scale the reflection component in the model. The abundance was allowed to vary from a solar profile in the final stages of the fitting.

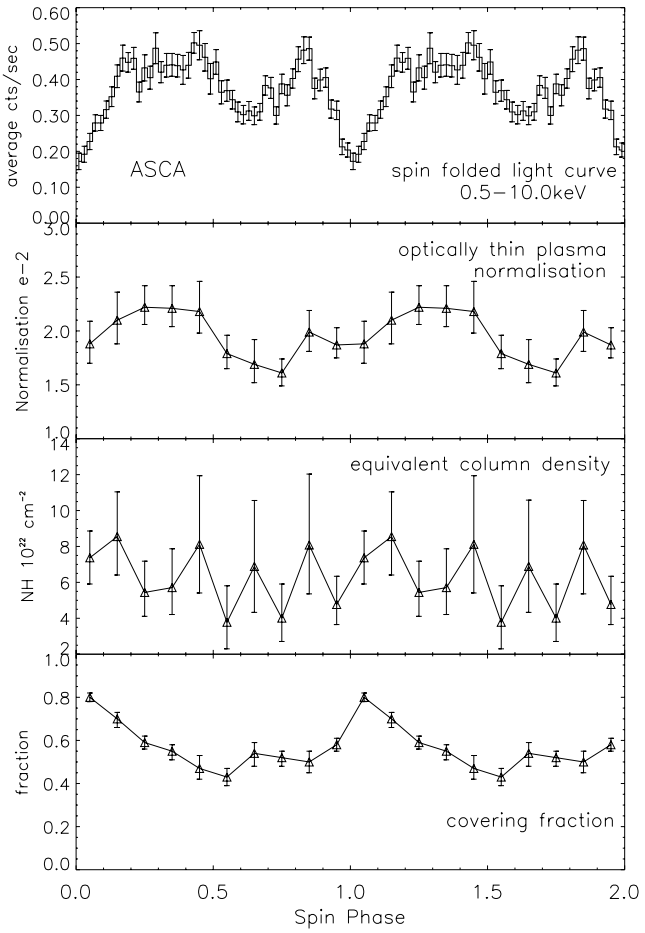

**Figure 5.** Results from spin-phase-resolved spectroscopy of *ASCA* data. $0.4 \leqslant \phi < 0.5$ is the reference spin phase. The plots from the top are the spin-folded light curve (included for clarity), the variation in the hard X-ray normalization, the column density of the partial covering absorber and its covering fraction.

### 5.2 The results

The *RXTE* spectral fitting was restricted to the spin phase range of the data to $0.1 \leqslant \phi < 0.5$, which corresponds to that portion of the spin cycle where a single emission site is visible (Potter et al. 1997). This phase range also excludes the dip centred on $\phi = .0$, which from *ROSAT* and *ASCA* data, has been shown to be caused by absorption. Models including homogeneous absorber components together with a CWRK emission component were found to be sufficient to produce an acceptable fit ($\chi^2_\nu \sim 0.89$) to this data using an estimated average viewing angle of $\sim 60^\circ$. This gave a white dwarf mass of 1.21 $M_\odot$ (Table 6). We discuss this further in Section 6.6.

## 6 DISCUSSION

In Section 4.2 we find that the spin phase modulation can be modelled well by a variation in the partial covering fraction of a neutral absorber at low energies and in the normalization at higher energies. Before we discuss this further, we briefly examine whether the modulation at both high and low energies can both be explained by a tall accretion shock.

In the case where the shock has a significant vertical extent, the lower (cooler) part of the shock could be obscured by the limb of the white dwarf at certain spin phases. The light curves will then have a larger amplitude at low energies than at high energies (e.g. Allan, Hellier & Beardmore 1998). The height of the accretion column, $H$, can be estimated from the relationship

$$H = 5.45 \times 10^8 \dot{M}_{16}^{-1} f_{-2} M_{\rm WD}^{3/2} R_{\rm WD}^{1/2}$$

(Frank, King & Raine 1992). Using the lower limit of the fractional area and the corresponding $\dot{M}$ derived in Section 6.4 (cf. Table 7) gives an upper bound of $H = 5.4 \times 10^7$ cm or $0.14 R_{\rm WD}$. However, the observational evidence suggests that PQ Gem has a significant magnetic field (Section 1), which implies that the shock height will be lower than this (e.g. CWRK) because of cyclotron cooling. This suggests that this mechanism is not the cause of the variation. However, the accretion regions are likely to be sufficiently structured (e.g. Potter et al. 1997) so that such a scenario cannot be excluded. On the other hand, because the spectral variations can be well modelled by a variation in covering fraction and normalization, we go on to consider this explanation in more detail.

### 6.1 Spin pulse modulation at higher energies

It is evident from an inspection of the 8–25 keV spin-phased *RXTE* light curve (Fig. 2) and the spin-phased normalization in the *ASCA* spectroscopy (Fig. 5) that they are broadly similar. As this emission is expected to be at most weakly beamed, this indicates that the variation in intensity is caused by changes in visibility of the X-ray emitting region as the white dwarf rotates. The phase of maximum emission therefore corresponds to the phase of maximum visibility of the emitting region. There is possibly a slight phase shift between the two curves, with a clear peak at $\phi = 0.2$ in the *RXTE* light curve, and a more extended maximum around $0.2 \leqslant \phi < 0.4$ in the *ASCA* normalization, but it is unclear given the uncertainties in the normalizations whether this is significant. Spin phases 0.2–0.4 also correspond to the phases at which the accretion region in the upper hemisphere is seen most close to face on (Potter et al. 1997, fig. 9). This suggests that this is the principal cause of the spin pulse modulation at higher energies.

### 6.2 Spin pulse modulation at lower energies

At lower energies, the maximum in the covering fraction of the absorber at $\phi = 0.0$ is the major effect on the soft X-ray light curve, while the local increase at $\phi = 0.6$ combined with the decrease in normalization at this phase causes the second minimum (Section 4.2). Potter et al. (1997) find that accretion occurs preferentially along field lines that thread the disc ahead of the accreting pole (their fig. 12). Material accreting along these field lines can therefore be identified as the source of the absorption at phase

**Table 6.** Results from fitting the CWRK model to the *RXTE* PCA spectrum ($0.1 \leqslant \phi < 0.5$). Details of the spectral fitting process are given in Section 5.

| Satellite | Detector | Angle (deg) | $N_{\rm H,cold}(1)$ $10^{22}$ cm$^{-2}$ | $\dot{m}$ (g cm$^{-2}$ s$^{-1}$) | rc ($10^7$ cm) | WD mass ($M_\odot$) | $\chi^2_\nu$ (dof) |
|---|---|---|---|---|---|---|---|
| *RXTE* | PCA | $\sim$60 | 5.2 | 2.3 | 9.5 | 1.21 (1.16–1.28) | 0.89 (46) |

**Table 7.** The effect fixing $\dot{m}$ to a range of values in the CWRK model during the spectral fitting. Details are given in Section 6.4.

| $\dot{m}$ (g cm$^{-2}$ s$^{-1}$) | WD mass ($M_\odot$) | $\chi^2_\nu$ (dof) | Unabsorbed flux (0.001–100.0 keV) (erg cm$^{-2}$ s$^{-1}$) | Luminosity ( erg s$^{-1}$) | $\dot{M}$ (g s$^{-1}$) | Fractional area |
|---|---|---|---|---|---|---|
| 0.5 | 1.20 (1.13–1.26) | 0.91 (52) | $6.3 \times 10^{-11}$ | $1.2 \times 10^{32}$ | $3.0 \times 10^{15}$ | $3.1 \times 10^{-3}$ |
| 1.0 | 1.21 (1.16–1.24) | 0.89 (52) | $6.4 \times 10^{-11}$ | $1.2 \times 10^{33}$ | $2.9 \times 10^{15}$ | $1.6 \times 10^{-3}$ |
| 5.0 | 1.22 (1.15–1.29) | 0.86 (52) | $6.6 \times 10^{-11}$ | $1.3 \times 10^{33}$ | $2.8 \times 10^{15}$ | $3.4 \times 10^{-4}$ |

0.0. Similarly, at $\phi = 0.6$, in the absence of absorption by the disc (cf. Section 6.4), the local increase in covering fraction is likely to be caused by absorbing material along field lines that intersect the line of sight to the lower pole (Potter et al. 1997, fig. 9).

Fig. 5 indicates that the change in absorption can be explained *entirely* by a change in covering fraction, with the column density of the absorber remaining constant. With reference to fig. 9 of Potter et al. (1997), at $\phi = 0.0$, all of the field lines between the disc and the accreting pole will intersect the line of sight. At $\phi = 0.2$, those field lines to the leading part of the accretion region will no longer intersect the line of sight, while by $\phi = 0.4$, only field lines to the trailing part of the accretion region will do so. If the column density through accreting field lines is $\sim 5 \times 10^{22}$ cm$^2$, the observed variation in covering fraction in Fig. 5 can be reproduced.

The accretion flow may be more finely fragmented along field lines feeding the leading edge of the accretion region. This would be expected because finely fragmented material is threaded by the magnetic field more easily than the larger denser inhomogeneities (e.g. Wickramasinghe 1988). From considerations of the packing fraction, the line of sight through more finely fragmented material is less likely to pass between gaps in the flow than in the case of the larger inhomogeneities. This effect would reproduce the high covering fraction at $\phi = 0.0$, and its subsequent decrease towards $\phi = 0.5$.

### 6.3 Accretion model

The accretion scenario we are proposing fits neither the standard occultation model of King & Shaviv (1984) nor the accretion curtain model of Rosen, Mason & Cordova (1988). The orientation of the accretion region at spin phase maximum is as predicted by the occultation model, but with absorption effects modifying the light curve significantly. In this it is similar to the 'weak-field/fast-rotator' model of Norton et al. (1999) with the symmetry of the accretion curtain about the magnetic axis modified by the leading field lines preferentially stripping material from the inner margin of the disc. The high (among IPs) magnetic field in PQ Gem and relatively high inclination and low dipole offset ($\sim 60^\circ$ and $\sim 30^\circ$, Potter et al. 1997) ensure that material on accreting field lines travels far enough out of the orbital plane to pass through the line of sight to the accretion region, causing the observed absorption effects. In this it differs substantially from EX Hya, which possesses a magnetic field $<1$ MG.

### 6.4 Occultation by the accretion disc?

Finally, we check whether the accretion disc can extend close enough to the white dwarf for it to have an affect on the X-ray light curves by obscuring the lower emission region.

Using the Ghosh & Lamb formulation (Li, Wickramasinghe & Rudiger 1996; Ghosh & Lamb 1978) the radius to the truncated inner edge of the accretion disc, $r_A$, is given by

$$r_A = 0.52 \mu_{WD}^{4/7} (2GM)^{-1/7} \dot{M}^{-2/7},$$

where $\mu_{WD}$ is the magnetic moment of the white dwarf.

The magnetic moment can be estimated from the relationship $B = \mu / r^3$. Using the fits to the *RXTE* data and the model of CWRK we found a best fit to the white dwarf radius, $R_{WD}$, of $3.8 \times 10^8$ cm. Hence, with a magnetic field strength, $B_{WD}$, of 15 MG (Piirola et al. 1993; Väth et al. 1996; Potter et al. 1997), $\mu_{WD} = 9.6 \times 10^{32}$ G cm$^3$. The accretion luminosity,

$$L_{acc} = GM\dot{M} / R_{WD}$$

where $M$ is the mass of the white dwarf and $L_{acc}$ is emitted mostly in the X-ray energy band, enables an estimation of the accretion rate, $\dot{M}$.

The unabsorbed spectral model from the analysis of the integrated spectrum (Section 4.1) extrapolated for the energy range 0.001–100.0 keV gives the X-ray flux at $3.1 \times 10^{-10}$ erg cm$^{-2}$ s$^{-1}$ which, taking the distance to PQ Gem of 400 pc (Patterson 1994), gives a luminosity of $6.0 \times 10^{33}$ erg s$^{-1}$ and hence a mass transfer rate, $\dot{M}$, of $1.4 \times 10^{16}$ g s$^{-1}$. This is typical for IPs (Warner 1995). The resulting $r_A = 1.3 \times 10^{10}$ cm or $\sim 34 R_{WD}$ may be too large given that an estimate of the distance to the first Lagrangian point is $\approx 200 R_{WD}$ (Plavec & Kratochvil 1964) (the main uncertainty in $r_A$ is in the magnetic moment $\mu_{WD}$). Nevertheless, it does indicate that with a system inclination of $60^\circ$ (Potter et al. 1997), the line of sight to the white dwarf surface is likely to be clear of the accretion disc at all spin phases, and this is unlikely to contribute to the cause of the covering fraction variation.

### 6.5 The size of the accretion region

Using the radius of the white dwarf, the specific mass accretion rate, $\dot{m}$ (2.3 g cm$^{-2}$ s$^{-1}$ cf. Table 6) and $\dot{M}$ determined above we can derive a fractional accretion area, $f$, of $9.0 \times 10^{-3}$. This is within the normal expectation of $0.001 \lesssim f \lesssim 0.02$ for an IP (Rosen 1992). However, from the *RXTE* data $\dot{M} = 2.9 \times 10^{15}$ g s$^{-1}$, which implies a fractional area of only $7.1 \times 10^{-4}$. Refitting the *RXTE* data to the model in which $\dot{m}$ was fixed at 0.5, 1.0 and 5.0 g cm$^2$ did not give a significant adverse effect on the fit ($\chi^2_\nu = 0.91$, 0.89, 0.86, respectively). Table 7 gives the implied fractional area and $\dot{M}$ for these $\dot{m}$ as well as the results from the spectral fitting. For a low specific mass accretion rate we find that the implied fractional area is consistent with the lower limit determined using previous observations.

### 6.6 The mass of the white dwarf

Previous determinations of the mass of the white dwarf in PQ Gem using an emission model fitted to *Ginga* data (Cropper et al. 1998, 1999) gave estimates $\geqslant 1.1$ $M_\odot$. In the case of the IP XY Ari, Ramsay et al. (1998) found that there was a good correspondence between the estimates given by this model and those from eclipse

mapping. In our work it is found that the *RXTE* data gives estimates that are very much better constrained than those made with the *ASCA* SIS data. The estimate from our *RXTE* data of $M_{\rm WD} = 1.21$ (1.16–1.28) $M_{\odot}$ corresponds well to that of 1.21 (>1.08) $M_{\odot}$ obtained with *Ginga* data. Although this appears to be unusually high, Ramsay (2000) found that the white dwarf in magnetic CVs were biased towards higher masses compared with isolated white dwarfs.
