1 SUMMARY

Aims AT9283 is used to treat patients with solid tumors and patients with leukaemia. However,
the maximum tolerated dose (MTD) for children with leukaemia remains unknown due to early
termination of the Phase I trial. The aim of this study was to develop a population model of
AT9283 to describe the pharmacokinetics in adults and children and to estimate the MTD in
children with leukaemia.

Methods Data from Phase I dose-escalation studies in adults and children were used to build a
population pharmacokinetic model (NONMEM v7.3). Potential covariates investigated included
body weight, body surface area (BSA), glomerular filtration rate (GFR), age and sex. Modelderived AUC was used to investigate the relationship between dose and exposure in adults and
children.

12 *Results* The plasma concentrations of AT9283 (n = 1770) from 92 patients (53 adults, 39

13 children) were used to build a two-compartment model with all pharmacokinetic parameters

14 scaled using body weight. Renal function (GFR), but not BSA, was a significant covariate for the

15 clearance of AT9283. In children with leukaemia (median weight 16 kg), a flat dose of 500

16 mg/72 h provided similar drug exposures at the MTD as the adult population. The estimated

17 MTD for children with leukaemia, therefore, is 30 mg/kg/72 h.

18 *Conclusion* For adults, GFR was a significant predictor of CL, whilst body-weight based dosing

19 was more useful than BSA in determining the drug exposure in children. The MTD was

20 estimated to be 30 mg/kg/72 h children with leukaemia.

1	WHAT IS ALREADY KNOWN ABOUT THIS SUBJECT
2	• Adults with leukaemia can tolerate a 10-fold higher dose of AT9283 than adults with
3	solid tumors.
4	• AT9283 is dosed by body surface area (BSA) but other factors influencing the
5	pharmacokinetics of AT9283 were not investigated
6	• The maximum tolerated dose (MTD) of AT9283 in children with leukaemia is not
7	known.
8	WHAT THIS STUDY ADDS
9	• A population pharmacokinetic model was used to combine the adult and children studies
10	to investigate factors that may influence the pharmacokinetics of AT9283.
11	• GFR and body weight are better predictors of clearance than BSA

- Doses of 30 mg/kg/72h in children with leukaemia would provide similar exposure
- 13 levels to that seen in adults with leukaemia at the maximum tolerated doses (MTD).

14

1. INTRODUCTION

3	The Aurora kinases (A, B and C) play a critical role in the cell mitotic process [1, 2]. Aurora
4	Kinase A is involved in centrosome function, mitotic entry and spindle assembly, whilst Aurora
5	Kinase B is a chromosomal passenger protein and is involved in chromatin modification,
6	microtubule-kinetochore attachment, spindle checkpoint and cytokinesis [1, 3]. Aurora Kinase C
7	is also a chromosomal passenger protein, and exhibits similar functions to Aurora Kinase B [3].
8	Aurora kinases are overexpressed in many cancers, therefore aurora kinase inhibitors are
9	promising anticancer drugs. Aurora kinase inhibitors may be particularly useful against
10	hematologic malignancies due to greater genetic homogeneity and greater proliferations rates
11	relative to solid tumours [4, 5].
12	
13	AT9283 (Astex Pharmaceuticals®) is a multi-targeted aurora kinase inhibitor found to be
14	a potent inhibitor of Aurora A, Aurora B and other kinases including JAK2, FLT3 and Abl
15	(T315I) [6]. In adults and children with solid tumours, AT9283 demonstrated significant aurora
16	kinase inhibition at tolerable doses with disease stabilization [4, 7]. However, the use of AT9283
17	is limited by its toxicity profile. Some of these dose-limiting toxicities (DLTs) included
18	neutropenia (grade 3-4), tumor lysis syndrome, bacterial infections cardiovascular and
19	gastrointestinal disorders [4, 7, 8].
20	AT9283 is administered as a continuous 72-hour infusion and is dosed by body surface
21	area (BSA). In Phase I studies of AT9283, the maximum tolerated dose (MTD) was identified
22	for adults with solid tumors $(27 \text{ mg/m}^2/72h)$ [7], adults with leukaemia $(324 \text{ mg/m}^2/72h)$ [8] and
23	for children with solid tumors (55.5 mg/m ² /72h) [4]. The Phase I study for children with

1	leukaemia, however, was terminated due to a slow recruitment rate. Only seven children were
2	recruited in this study and the maximum dose level reached was 69 mg/m ² /72h.
3	The pharmacokinetics of AT9283 was previously investigated using a non-
4	compartmental approach in each population group [4, 7, 8]. Each pharmacokinetic study noted
5	large inter-individual variability (IIV) in the pharmacokinetics of AT9283, even after adjusting
6	doses for BSA [4]. Furthermore, the increase in exposure to AT9283 was proportional to
7	absolute administered dose, rather than the BSA-based dosing level [4]. A better understanding
8	of the relationship between AT9283 doses and plasma concentration, as well as determinants of
9	drug exposure, will enable doses of AT9283 to be optimized for each patient population.
10	
11	Population pharmacokinetic modelling and simulation is an industry standard method of
12	investigating the pharmacokinetics of a drug to identify measurable pathophysiological factors
13	influencing the pharmacokinetics of the drug [9]. In this study, the data from adult and children
14	studies were pooled to describe the pharmacokinetics in these population groups. Furthermore,
15	this population model was used to simulate doses in children with leukaemia and to estimate
16	what the MTD would be in this population.
17	
18	2. METHODS
19	
20	2.1 Datasets and study design
21	Phase I data for this investigation originated from four separate pharmacokinetic studies in adults
22	([7, 8]; NCT00443976, NCT00522990) and children ([4]; NCT0098568, NCT01431664) and
23	were sponsored by Astex Pharmaceuticals and Cancer Research UK., respectively. These dose-

1 escalation studies were designed to investigate the safety and tolerability of AT9283 in each 2 population group and to establish a dose for Phase II studies (Table 1). The conventional 3 + 33 study design was used for the adults (solid tumor and leukaemia) and children with leukaemia, 4 whilst the rolling six design was used for children with solid tumors. 5 Written informed consent was obtained from all patients and from all parents and guardians of 6 children. These studies were approved by the local ethics committees for each trial centre 7 (various locations in the U.S. and the U.K.) [4, 7, 8, 10] and were conducted to Good Clinical 8 Practice in accordance with the Declaration of Helsinki and its amendments. 9 10 2.2 AT9283 dosing 11 AT9283 was administered as a continuous three-day (72 h) i.v. infusion every 21 days via central 12 venous access. The doses of AT9283 were adjusted according to body surface area (BSA), which 13 was calculated using the Mosteller formula [11]. The maximum tolerated dose (MTD) was 14 defined as the highest dose that could be given based on the incidence of dose-limiting toxicities 15 (DLTs). For the 3 + 3 design, the MTD was defined as the dose given to three patients with less than one patient experiencing a DLT. For the rolling six design, the MTD is the dose given to six 16 17 patients with less than one patient experiencing a DLT.

18

19 **2.3 AT9283 concentrations**

Blood samples for pharmacokinetic analyses were collected during the first and second cycle for
the adult studies and during the first cycle for studies conducted in children. The time-points for
blood collection are outlined in Table 1. The concentrations of AT9283 were quantified using a

1	validated LC-MS/MS assay [4] (Astex Investigator's Brochure) over a calibration range of 0.1 –
2	500 ng/mL. The lower limit of quantification (LLOQ) was 0.1 ng/mL.
3	
4	2.4 Population modelling
5	Population pharmacokinetic analyses were conducted using the population modelling package
6	NONMEM® 7.3.0 (ICON Development Solutions, Hanover, MD, USA) [12] with first-order
7	conditional estimation method with interaction (FOCE-I). Model development was managed
8	using Perl-Speaks-NONMEM 3.5.3 [13], Pirana 2.8.1[14] and R (Version 3.2.5) [15]. Model
9	selection was informed by using the objective function value (OFV, -2log likelihood) [16],
10	whereby a reduction of \geq 3.84 points in OFV was considered statistically significant (<i>P</i> < 0.05
11	with d.f. = 1, approximate asymptotic x^2 -distribution).
12	
13	2.4.1 Structural and statistical model
14	The pharmacokinetics of AT9283 was tested using one-compartment and two-compartment
15	structural models. The inter-individual variability (IIV) is the unexplained random variability
16	between individuals, which was described using a log-normal distribution (Eq. 1):
17	$P_i = P_{TV} \times exp^{(n_i)} \tag{1}$
18	where P_i is the pharmacokinetic parameter of the i^{th} individual. P_{TV} is the typical population
19	parameter value, n_i is the IIV in the i th individual with a distribution of N(0, ω_{IIV}^2).
20	Different error models were tested to describe the residual unexplained variability of the
21	data (additive, proportional, mixed, exponential, log-transformation). A separate residual error
22	model was also evaluated for each of the studies to account for variability in the assays. Only 3%

of the observations of the dataset were below the limit of quantification, and were therefore
 excluded from the analysis.

5			
\mathcal{I}			

2.4.2 Covariate model

6 Potential covariates were evaluated by visual inspection of the empirical Bayes estimates (EBEs)

7 against the covariates and by step-wise inclusion into the model. The covariates investigated

8 included measurements of body size (body weight, BMI, lean body weight, BSA, fat-free mass

9 [17]), cancer type and kidney function (glomerular filtration rate, GFR). The backward

10 elimination of covariates was used to confirm covariate selection, whereby an increase in OFV

11 (>6.63, P <0.01) was required.

12 For continuous covariates, linear, piecewise-linear, exponential and power relationships were

13 investigated. There were only two children aged under 2 years, therefore a model to describe CL

14 maturation with age for children under 2 years was not needed.

An allometric weight model was used to standardize all pharmacokinetic parameters to a body
weight of 70 kg [18]. The allometric weight model for the clearance parameters and volume
parameters are shown in Eq. 2 and 3, respectively.

$$18 F_{CL} = \left(\frac{WT}{WT_{STD}}\right)^{0.75} (2)$$

$$19 F_V = \left(\frac{WT}{WT_{STD}}\right)^1 (3)$$

Where a standard weight value of 70 kg (WT_{STD}) was used to normalize pharmacokinetic
parameters in adults and children.

For adults, GFR was estimated using the Modification of Diet in Renal Disease (MDRD)
formula for adults [19] (Eq. 4):

$$GFR (mL/min/1.73m^{2})$$

$$= 175 \times [serum creatinine (\mu mol/L)]^{-1.154} \times Age (years)^{-0.203} \times k$$

$$(4)$$

4 where k is 1 for males and 0.742 for females.

5 For children aged under 18 years, the bedside Schwartz formula [20] was used (Eq. 5):

6
$$GFR (mL/min/1.73m^2) = \frac{41.3 \times height (cm)}{serum \, creatinine \, (\mu mol/L) \times 0.01131}$$
7 (5)

8 2.4.3 Model evaluation

9 The model was evaluated by visual inspection of goodness of fit plots of the observed and predicted 10 concentrations and conditional weighted residuals (CWRES). The final model performance was examined by using prediction-corrected visual predictive checks (VPCs) to compare the 5th, 50th 11 and 95th percentiles of the observed concentrations and simulations of concentration-time profiles 12 13 (1,000 replicates) from the final model [21]. A nonparametric bootstrap method [22] (n = 1,000)14 was used to study the uncertainty of all pharmacokinetic parameter estimates in the final model to 15 obtain the median and 95% confidence interval of the parameter estimates. Significant differences 16 between baseline measurements were evaluated using the unpaired t test in R. A P value of <0.05 17 was considered statistically significant.

18

19 **2.5 AT9283 exposure**

The final model was used to calculate the area-under the curve $(AUC_{0-\infty})$ of AT9283 using posthoc estimates of CL $(AUC_{0-\infty} = \text{Dose/CL})$. Using the final model, stochastic simulations were performed to simulate concentration-time profiles (n = 1,000) using the median dose and median BSA for patients who were administered the MTD dose. The concentrations of AT9283 at the MTD were compared to investigate the variability in the drug exposure for the different patient
 groups.

3 For children with leukaemia, dosing simulations were conducted to target a similar range of 4 $AUC_{0-\infty}$ to that seen in adults with leukaemia. Since there were limited data for children with 5 leukaemia, the exposure-toxicity relationship was assumed to be the same in adults and children. 6 7 8 3. Results 9 10 **3.1 Study population** 11 A summary of the patient demographics is shown in Table 2. The dose administered ranged from 4.5 mg/m²/72 h to 486 mg/m²/72h. For children with leukaemia, the trial was terminated at a 12 13 dose of 69 mg/m²/72 h. About half of the adult population had mild to moderately reduced 14 kidney function (GFR <90 mL/min/1.73m²), whilst children had predominately healthy kidney 15 function (GFR $> 100 \text{ mL/min}/1.73\text{m}^2$) (Table 2, Supplementary Figure 1). Compared to children (GFR, 132.9 [47.4 - 299.4] mL/min/ $1.73m^2$, median [range]), most adults had some form of 16 17 kidney dysfunction (GFR, 77.1 [31.9 - 170.5] mL/min/1.73m²; P <0.001). As expected, there was larger variability in the BSA in children than in adults. Children with leukaemia were 18 19 younger (difference between the medians of 7 years, P < 0.01) and had a smaller BSA (0.34 m², 20 P < 0.001), compared to children with solid tumors. 21

22 **3.2 Population model**

A total of 1770 observations from 92 individuals were used for population analyses. This dataset was best described using a two-compartment model. All observations were log-transformed and the residual variability was described using a combined additive and proportional error model for the adult population and an additive error model for children. The separate error model for the adults and children was used to account for site-specific variability in sample collection and the analytical assays (ΔOFV -118.1). The IIV was estimated on all parameters. The correlations between the IIV of each parameter was estimated using a full covariance matrix.

8

9 The influence of body size on the pharmacokinetic parameters for adults and children 10 was best described using an allometric model with body weight for CL. An empirical GFR 11 power model was used to describe the effect of renal function on clearance, normalized to a 12 standard of 6 L/h (100 mL/min), which significantly improved the model (ΔOFV -66.3, reduced 13 IIV by 1.6%). There were no significant differences between the CL of AT9283 in patients with 14 solid tumors (25.5 [9.0 – 66.7] L/h) and patients with leukaemia (27.8 [4.3 - 48.0] L/h, P =15 0.12). Cancer type was not a significant covariate in the model for any pharmacokinetic 16 parameter (did not reduce the IIV). The final equations for CL and $V_{\rm C}$ were (Eq. 6 and 7):

17
$$CL = \theta_{CL} \times \left(\frac{WT}{WT_{STD}}\right)^{0.75} \times \left(\frac{GFR}{GFR_{STD}}\right)^{\theta_{EC}}$$
 (6)

18
$$V_C = \theta_{VC} \times \left(\frac{WT}{WT_{STD}}\right)^1$$
 (7)

19 Where θ_{EC} is the estimated power parameter for GFR.

20

The goodness-of-fit plots showed that the final model described the pharmacokinetics of AT9283 in adults and children with no apparent bias (Figure 1). There was good agreement between the observed concentrations and model predictions for children throughout different weight categories 1 (Supplementary Figure 3). The VPCs revealed good agreement between the model simulations 2 and the 5th, 50th and 95th percentiles of the observations and the model adequately described the 3 time-course of AT9283 concentrations (Figure 2). The simulated prediction intervals for children 4 post-infusion are wide due to the lack of data collected after 80 hours. All parameters were 5 estimated with acceptable precision (residual standard error <30%), without any significant 6 shrinkage (<30%) and the non-parametric bootstrap indicated that the model was robust (Table 3).

- 7
- 8 **3.3 AT9283 exposure**
- 9

10 AT9283 exposure at the MTD was investigated using the median covariate values of each 11 population group (Table 4, Figure 3). In the solid tumor studies, the MTD was $27 \text{ mg/m}^2/72h$ for 12 adults and 55.5 mg/m²/72h for children. Using the median BSA, these doses are equivalent to 13 median doses of 51 mg/72h and 68 mg/72 h, in adults and children, respectively. The median 14 MTD in adults with leukaemia was 10-fold higher (567 mg/72h) than for patients with solid 15 tumours, with a median $AUC_{0-\infty}$ of 20, 956 h.ng/mL (4,774–76,805 h.ng/mL, range). 16 Children with leukaemia (median weight 16 kg) only reached an $AUC_{0-\infty}$ of 2,949 h.ng/mL (539 17 - 9,988 h.ng/mL, range) at the median maximum dose administered (51 mg/72h). To reach an 18 MTD drug exposure comparable to that in adults with leukaemia, children with leukaemia would 19 require doses of 500 mg/72 h, to achieve an $AUC_{0-\infty}$ of 38,254 h.ng/mL (9694 – 124,430 20 h.ng/mL) (Figure 3). To account for the range of weights in children, doses of 30 mg/kg/72 h 21 would provide a more consistent exposure in children rather than a flat dose of 500 mg/72 h22 (Supplementary Figure 4). Figure 4 shows the differences in the drug exposure with varying 23 GFR and weight at a dose of 30 mg/kg/72 h. A weight-based dosing regimen reduced the

variability in the drug exposure for children, whilst the effect of GFR would be significant only
 for patients with poor kidney function.

- 4

4. **DISCUSSION**

6

5

7 The primary objective of oncology Phase I dose-finding studies is to determine the MTD and the 8 dose level below the MTD is usually carried forward to Phase II oncology trials [23, 24]. However, 9 there are numerous issues that may prevent the completion of Phase I oncology trials. Firstly, the 10 recruitment rate may be slow because only patients who are resistant to standard treatment are 11 eligible. Secondly, Phase I oncology trials have a long dose-escalation scheme, with initial doses 12 far below the MTD to minimize toxicity, which consequently increases the number of patients 13 treated at sub-therapeutic doses. In the case of the AT9283 trial in children with leukaemia, the 14 lowest target inhibitory dose was used as the starting dose due to some concerns with cardiotoxicity 15 in the adult studies [8]. However, the combination of slow recruitment with a coincident increase 16 in competing studies and long dose-escalation scheme eventually led to the termination of the trial. 17 The population pharmacokinetic approach was therefore used to estimate what the MTD would be 18 for children with leukaemia. One of the main advantages of using the population approach is that 19 the data from adults and children can be combined to provide robust estimates of the 20 pharmacokinetics of AT9283 (Figure 1 and 2).

The adult and child datasets were combined by adjusting all pharmacokinetic parameters for body weight. Compared to BSA, the inclusion of body weight as a covariate provided the largest drop in OFV. Body weight is also the preferred covariate for body size because it is

directly measurable and estimating BSA for small children is difficult [25]. Furthermore, renal
function as estimated by GFR, was found to be a significant covariate for CL, consistent with the
finding that 20-30% of the drug is eliminated in the urine [7].

4 The absolute MTD administered to adults and children with solid tumours were similar, 5 after accounting for the differences in BSA. Previous studies have reported a much higher MTD 6 for children with solid tumours (55.5 mg/m²/72h) [4] compared to adults with solid tumors (27 7 $mg/m^2/72h$) [7], which corresponded to mean absolute doses of 67.7 mg/72 h and 51.3 mg/72h in 8 children and adults, respectively. Children with solid tumors had an approximately 25% higher 9 AUC compared to adults with solid tumors (Figure 3, Supplementary Figure 2). Considering that 10 most responses occur within 80% and 120% of the MTD [23, 24, 26], the potential MTD dose 11 range in adults with solid tumors (41 to 61.6 mg/72 h, range) is comparable to the MTD dose 12 range in children with solid tumors (54.2 to 81.2 mg/72 h).

13

14 The main dose limiting toxicity (DLT) of AT9283 was febrile neutropaenia [7], therefore 15 patients with leukaemia can tolerate much higher doses of AT9283. In adults with leukaemia the MTD (567 mg/72 h) resulted in a 10-fold higher drug exposure (median $AUC_{0-\infty}$: 20, 956 16 h.ng/mL; range, 4,774 – 76, 805 h.ng/mL) compared to adults with solid tumors (Figure 3). To 17 18 achieve this same level of exposure, we estimated that the MTD would need to be 10-fold higher 19 than the maximum dose administered to children with leukaemia. We have found that doses of 20 30 mg/kg/72 h are suitable for children to obtain a similar drug exposure to that see in adults 21 with leukaemia at the MTD.

The AUC of AT9283 is higher for patients with poor kidney function and for patients
with large body size (Figure 4). Since children enrolled in the Phase I studies have predominately

1	normal kidney function, GFR was a more relevant predictor of AT9283 exposure in adults (GFR
2	77.1 [31.9 – 170.5] mL/min/1.73m ²). In contrast, body weight is a more relevant predictor of
3	drug exposure in children, particularly for children at the extremes of body weight (Figure 4).
4	
5	A limitation of this study is the small sample size in children with leukaemia ($n = 7$).
6	Children with leukaemia were also the youngest population group and had the smallest body
7	size. Since there is limited data on very young children, large variability in the concentrations of
8	AT9283 was observed in our simulations of children with leukaemia (Figure 3).
9	
10	We have provided an estimate of the MTD in children with leukaemia, which is based on
11	achieving a target AUC. However, the identified MTD in Phase I studies was based on the
12	incidence of DLTs at discrete dosing levels. The MTD represents the dose for which the
13	percentage experiencing the DLT ranges from 15% to 70%, which may differ significantly from
14	the actual MTD [27]. Since Phase I oncology studies only assessed the toxicity profile of
15	anticancer drugs, it is not known how the MTD relates to the efficacy of AT9283. Knowledge of
16	the exposure-response relationship of AT9283 would provide a better indication of the target
17	AUC required to achieve an optimal response.
18	
19	4.1 Conclusions
20	The population pharmacokinetic analysis provides a method of shortening the time to reach the
21	MTD by potentially reducing the number of patients enrolled in dose-escalation trials and the
22	number of patients treated at sub-therapeutic doses. We have found weight to be a better

23 predictor of the pharmacokinetics of AT9283 rather than BSA for children, whilst GFR is a

1	relevant predictor of CL, for adults. If the Phase I trial was to be completed in children with
2	leukaemia, we estimated that the MTD for children with leukaemia would be 30 mg/kg/72 h,
3	which is about 10-fold higher than the maximum dose tested.

Figure 1. Goodness-of-fit plots of the final model. The open circles are the observations from the
adult dataset and the open triangles are the observations from the children. The population
prediction and individual prediction plots are shown with the line of identity (black) and a linear
regression line (blue). Plots of CWRES are shown with a loess smooth (blue line). *CWRES*,
conditional weighted residuals.

8

9 Figure 2. Prediction-corrected visual predictive checks (VPCs) of the AT9283 concentrations

10 stratified by population. The dots are the observations plotted with the median observed AT9283

11 concentrations (red line) and the 5th and 95th percentiles of the observed concentrations (dotted

12 blue lines). The shaded areas are the 95% confidence intervals of the 5th, 50th and 95th percentiles

- 13 of the simulated concentrations.
- 14

15 Figure 3. Simulations of AT9283 exposure at the MTD in (a) adults with solid tumours, (b)

16 adults with leukaemia, (c) children with solid tumors, (d) and the estimated MTD in children

17 with leukaemia (500 mg/72h). The black solid lines are the median AT9283 concentrations and

18 the shaded areas are the 90% prediction intervals of the simulations.

19

Figure 4. Simulated median AT9283 concentrations at a dose of 30/kg/72 h over a range of GFR
and weight. *GFR* glomerular filtration rate, *WGT* body weight.
