KEYWORDS

Multiple sclerosis; relapsing/remitting; quantitative MRI; NODDI; diffusion-weighted MRI; axonal loss.

ABSTRACT

Background: Multiple sclerosis (MS) affects both brain and spinal cord.

However, studies of the neuraxis with advanced MRI are rare because of long acquisition times. We investigated neurodegeneration in MS brain and cervical spinal cord using neurite orientation dispersion and density imaging (NODDI).

Objective: to investigate possible alterations, and their clinical relevance, in neurite morphology along the brain and cervical spinal cord of relapsing-remitting MS patients.

Methods: 28 relapsing-remitting MS patients and 20 healthy controls underwent brain and spinal cord NODDI at 3T. Physical and cognitive disability was assessed. Individual maps of orientation dispersion index (ODI) and neurite density index (NDI) in brain and spinal cord were obtained. We examined differences in NODDI measures between groups and the relationships between NODDI metrics and clinical scores using linear regression models adjusted for age, sex and brain tissue volumes or cord cross-sectional area.

Results: Patients showed lower NDI in the brain normal-appearing white matter and spinal cord white matter than healthy controls. In patients, a lower NDI in the spinal cord white matter was associated with higher disability.

Conclusions: Reduced neurite density occurs in the neuraxis but, especially when affecting the spinal cord, it may represent a mechanism of disability in MS.

INTRODUCTION

Neurodegeneration represents a major component of multiple sclerosis (MS) pathology and it can affect the whole neuraxis¹, brain and spinal cord, from the relapsing-remitting stage of MS². Quantitative magnetic resonance imaging (MRI) biomarkers of the brain³ and spinal cord⁴ may reflect neurodegeneration *in vivo* and, thus, may be used as outcome measures in clinical trials targeting neuroprotection in MS⁵. However, it is unclear whether brain or spinal cord pathological alterations are the main correlates of disability in MS⁶. To address

this question, studies of the neuraxis with quantitative MRI should be carried out, but these are rare because of the long acquisition times.

Neurite orientation dispersion and density imaging (NODDI) is a multi-compartmental model of diffusion MRI⁷ that is more specific than DTI in capturing the microstructural substrates possibly underpinning neurodegeneration⁸. Specifically, NODDI provides two indices of neurite morphology, the neurite density index (NDI) and the neurite orientation dispersion index (ODI). NDI estimates the fraction of axons and dendrites within the neural tissue: it is primarily sensitive to axonal loss, and therefore neurodegeneration, with other changes, such as demyelination, also contributing to its value⁹. ODI quantifies the variability of neurite orientations: a high orientation dispersion occurs when neurites are dispersed in space; therefore, it becomes meaningless when measured in voxels corresponding to cerebrospinal fluid (CSF).

A few studies have applied NODDI to the brain of MS patients. They all reported a decrease in the NDI in both the white matter (WM) lesions¹⁰⁻¹² and normal-appearing WM¹⁰⁻¹³ in MS patients compared with healthy controls (HCs). ODI was also found to be altered, predominantly in WM lesions, but in different directions depending on the study¹⁰⁻¹². Alterations in NODDI indices were

correlated with physical disability, as measured by the Expanded Disability Status Scale (EDSS)^{11,13}.

However, no study has investigated correlations between NODDI alterations and cognitive impairment,¹⁴ which is associated with neurodegeneration,¹⁵ and the impact of WM lesions on the observed NODDI abnormalities is unknown. Additionally, a previous study¹¹ used a unique 3T scanner with gradient strength up to 300 mT/m, a technology not widely available in the clinical setting, whose results are difficult to compare and/or to replicate.

Another key question is whether NODDI can be used to investigate *in vivo* neurodegeneration in the spinal cord of MS patients. We have previously demonstrated the feasibility of NODDI application to the healthy spinal cord¹⁶. A preliminary observation in a small number of patients (N=6)¹⁷ has suggested abnormal ODI and NDI metrics in the spinal cord of MS patients when compared with controls.

Thus, a characterization of the neurite density and orientation dispersion in the whole neuraxis of MS patients is lacking, although this would contribute to understanding if the brain and spinal cord share common pathological abnormalities. Therefore, we applied NODDI to the brain and cervical cord of

relapsing-remitting MS (RRMS) patients and HCs, using a clinical 3T scanner. To determine if the underlying abnormalities in the neurite morphology, as captured by NODDI, contribute to disability, we assessed the correlations between NODDI indices and physical and cognitive disability.

MATERIALS AND METHODS

Patients' characteristics and clinical assessments

We enrolled 28 consecutive patients who fulfilled the following inclusion criteria: diagnosis of RRMS, age between 18 and 65 years, absence of relapses or corticosteroid treatment in the three months before imaging and no other known medical condition affecting the central nervous system (CNS). Twenty age- and sex-matched HCs were also recruited.

Patients were assessed with the EDSS. All subjects underwent the MS functional composite (MSFC) score, which includes the 9-Hole Peg Test, the Timed 25-Foot Walk test and the Paced Auditory Serial Addition Test, as well as the brief cognitive assessment for MS (BICAMS)¹⁸ including Symbol Digit Modalities Test (SDMT), California Verbal Learning Test-II (CVLT-II) and Brief Visuospatial Memory Test-Revised (BVMT-R). Anxiety and depression were tested as possible confounders with the Hospital Anxiety and Depression Scale (HADS)¹⁹.

For the MSFC total score, z-scores were calculated according to the National Multiple Sclerosis Society Task Force guidelines²⁰.

Written informed consent, approved by the local research ethics committee, was obtained for all participants.

MRI protocol

Brain and spinal cord MRI scans were performed in the same session at 3T using a Philips Achieva MRI system (Philips Healthcare, Best, the Netherlands) with RF multi-transmit technology, Quasar Dual gradient set of 40/80 mT/m and with a 32-channel coil for brain acquisition and a 16-channel neurovascular receive-only radiofrequency coil for the spinal cord (Table 1). The spinal cord protocol was acquired before the brain protocol in all subjects.

Brain NODDI cardiac-gated diffusion-weighted images were acquired using a spin-echo echo-planar imaging sequence. The diffusion protocol consisted of 3 b-shells and gradient directions isotropically distributed: b-value=300s/mm² and 8 directions; b value=1000 s/mm² and 30 directions; b value=2855s/mm² and 60 directions. Eight interleaved non-diffusion-weighted (b=0) images were also acquired.

The cervical cord was imaged in the axial-oblique plane (i.e., slices perpendicular to the longitudinal axis of the cord) with the center of the imaging volume positioned at the level of C2-3 intervertebral disc. Moreover, to reduce

motion artifacts during scanning and improve image quality, an MR compatible cervical collar was worn by all subjects²¹.

For NODDI, the acquisition protocol for all scans relied on a reduced field-of-view (FOV), cardiac gated PGSE ZOOM-EPI sequence, acquiring two diffusion-weighted high angular resolution imaging (HARDI)²² b-shells of thirty measurements at $b=1000\text{s/mm}^2$ and sixty measurements at $b=2855\text{s/mm}^2$ and 3 interleaved $b=0$ measurement, respectively¹⁶. A total of 20 slices were acquired with a total acquisition time of approximately 35 min. Simulations, not included in this paper, revealed that 3 $b=0$ measurements suffice to estimate the correct $b=0$ offset level 95% of times, with a precision of 7.8%, against precision of 4.9%, with 8 $b=0$ measurements, with realistic spinal cord SNR levels^{16,23}.

Conventional MRI post-processing

T2 hyperintense lesions were outlined in each subject using the semi-automated edge finding tool from JIM v6.0 (Xinapse systems, Aldwinckle, UK) and the lesion volume (ml) was computed. The lesion masks were co-registered to the 3D-T1 images²⁴ and then the 3D-T1 images were filled using a non-local patch match lesion filling technique²⁵. For brain extraction, tissue segmentation and parcellation, we used Geodesic Information Flows (GIF)²⁶.

The upper cervical cord cross-sectional area (CSA) was measured from the 3D-FFE scans of the cervical cord: an active surface model was applied using JIM v6.0 to obtain the CSA by averaging the area of three contiguous 5mm axial slices, centered on C2/3 disc^{27,28}. Spinal cord lesions were identified as delineated areas of hyperintensity on the 3D-FFE sequence and counted.

Diffusion-weighted data processing

Brain

Each diffusion-weighted image was corrected for eddy current-induced distortions and subject movements using eddy in FSL6.0(FMRIB, Oxford, UK)²⁹. For the NODDI fitting, we used the Matlab (The MathWorks, Inc., Natick, Massachusetts, USA) NODDI toolbox (http://nitrc.org/projects/noddi_toolbox) with the default settings to generate ODI and NDI.

The segmented tissue masks and lesion masks were then registered to the NODDI maps to extract the tissue-specific NODDI values.

Spinal cord

Diffusion-weighted data were pre-processed and corrected for motion¹⁶. For each subject, the whole cord was segmented on the mean b=0 volume by using a semi-automatic active surface method²⁷ implemented in JIM V6.0. The fitting cord mask was then eroded slice-by-slice and cropped to the 6 central slices creating the whole-cord mask. Subsequently, the spinal cord grey matter (GM)

and WM, as well as dorsal, lateral and ventral WM sub-regions masks, were manually outlined in each subject on the average DW image which was obtained by averaging the diffusion-weighted images acquired for gradient directions at angle less or equal to 50 degrees with respect to the longitudinal axis of the spinal cord, according to the procedure described by Kearney and colleagues³⁰ (Supplemental Material).

The NODDI model was fitted within the whole cord mask (before slice wise erosion) by using the NODDI MATLAB toolbox. NODDI indices were then calculated within the manually segmented spinal cord tissue masks. Voxels with isotropic volume fraction (i.e. CSF voxels) >0.99 were excluded from the analysis.

All the brain and spinal cord NODDI images underwent quality checks and were excluded based on motion artifacts, noticeable signal drifts on the $b=0$ signal.

Examples of the brain and spinal cord NODDI maps are given in Figure 1.

Statistical analysis

Group differences in demographic characteristics were assessed using the two-sample t-test for continuous variables and the chi-square test for categorical variables.

We applied a linear regression model to investigate the differences between

patients and HCs in brain tissue volumes (i.e., WM and GM tissue volumes), CSAs, clinical tests and NODDI metrics, adjusting for age and sex. When looking for differences in NODDI metrics, the models were repeated including specific brain tissue volumes (when brain comparisons were tested) or CSA (when spinal cord comparisons) to account for the possible influence of atrophy. In patients, we used linear regression models to investigate associations between NODDI metrics and brain volumes and spinal cord CSA, and disability (i.e., MSFC and BICAMS), adjusting for age and sex. Only the NODDI metrics and the clinical tests that showed significant differences between patients and HCs were entered in these models. In case of significant associations between NODDI metrics and disability scores, the regressions were re-run adjusting for the brain parenchymal fraction and the spinal cord CSA. Since the EDSS score and lesion loads (brain lesion volume and spinal cord lesion count) are not normally distributed, we used the Spearman's rho correlation coefficient for the associations between NODDI metrics and these parameters.

Stata v. 14.1 (Stata Corporation, College Station, Texas, USA) was used. Results associated with a $p < 0.05$ were considered statistically significant and reported. Due to the exploratory nature of the study, the statistical inference of multiple comparisons was not performed.

RESULTS

Out of 28 patients and 20 HCs who underwent the MRI protocol (Table 2), we included into the analysis the brain MRI data of 24 patients and 16 HCs and the spinal cord data of 27 patients and 18 HCs (the remainder scans were discarded after quality checks and/or for incomplete MRI protocol).

In comparison to HCs, RRMS patients showed brain and spinal cord atrophy (Table 2) as well as lower scores on the BICAMS, and MSFC (Table 3). The BICAMS and PASAT scores did not correlate with the HADS scores.

Patients showed lower NDI in the brain normal-appearing WM than HCs ($B = -0.021$, 95% confidence interval (CIs): -0.041 to -0.002 , $p=0.032$). In the spinal cord, patients showed lower NDI in the whole WM ($B = -0.07$, 95% CIs: -0.11 to -0.03 , $p=0.001$), particularly in the dorsal and lateral WM sub-regions, and a lower ODI in the dorsal WM ($B = -0.04$, 95% CIs: -0.07 to -0.1) than HCs (Figure 2). These differences remained significant after adjusting for WM brain tissue volume and CSA, respectively (Table 4). NDI was lower in the spinal cord GM of RRMS patients than HCs ($B = -0.04$, 95% CIs: -0.07 to -0.006 , $p=0.021$), but this difference became not significant when adjusting for CSA.

In patients, a lower NDI in the whole WM and dorsal sub-region of the spinal cord correlated with higher EDSS score ($r_s=-0.46$ $p=0.015$ and $r_s=-0.48$, $p=0.012$, respectively) (Figure 3), while there was a weak correlation between lower ODI in the dorsal column and higher EDSS ($r_s=-0.39$ $p=0.045$).

In patients, lower NDI in the brain normal-appearing WM was associated with a higher brain lesion load ($r_s=-0.52$, $p=0.009$)(Table 5-6).

DISCUSSION

Using a clinical scanner, we found evidence of neurite integrity loss, as captured by NDI, in both the spinal cord and the brain of patients with MS when compared to HCs.

In the cervical cord of MS patients, a reduced density of nerve fibers (NDI) was detected in the whole cord, especially in the lateral and dorsal WM columns. We also found a lower dispersion of neurites (ODI) in the dorsal columns of patients when compared to controls, as opposed to the finding of a different research group, which studied only six MS patients¹⁷. A low ODI value may be related to a reduction in the angular variations of axons, possibly caused by demyelination, as well as to the contribution of WM lesions, not excluded in our

analysis, that have shown low ODI values in previous studies from our group^{10,31} and are often present in the dorsal columns of MS patients³².

The results of the brain NODDI comparisons between groups mirrored the spinal cord findings, with a lower NDI in the brain normal-appearing WM of patients when compared to HCs. In the brain, we found a relationship between lower NDI and higher lesion load, thus extending the findings of previous studies^{11,13}. As alterations in the normal-appearing WM of MS patients can be characterized by diffuse axonal injury³³, our results may support the hypothesis that this axonal damage is due to the degeneration of axons transected in focal lesions³⁴.

The most interesting result of our study is that lower NDI in the spinal cord WM was associated with greater disability, as measured by EDSS. This suggests that a reduced neurite density, which is a known component of neurodegeneration, may contribute to neurological impairment in MS. When reflecting on the absence of a significant correlation between low neurite density and increased disability in the brain, it is important to consider that long axons are highly compacted in the WM columns of the spinal cord, where they mediate neurological functions. Therefore, the alterations in the axon

microstructure detected by NODDI in the spinal cord WM are more likely to correlate with the EDSS, which is heavily weighted towards walking ability, than the global reduced NDI observed in the brain normal-appearing WM. This interpretation is supported by a previous study carried out in MS which reported that the EDSS was related to reduced NDI only in specific brain WM regions, such as the corpus callosum and internal capsule, where long-tract axons are found¹³.

Finally, for the first time, we investigated possible correlations between cognitive performance and NODDI metrics. However, measures of cognition did not correlate with abnormal NODDI parameters. Since patterns of orientation abnormalities detected by diffusion imaging in the cortex seem to be related to cognitive functions³⁵, further studies analyzing NODDI in specific cortical regions and linking them with the corresponding cognitive domains are needed.

Limitations

A possible limitation of our analysis is that we could not exclude MS lesions from the spinal cord NODDI maps; therefore, it is expected that NDI from the lesional tissue contributes to the observed reduced NDI. However, the relationship between spinal cord NDI and disability was independent of spinal

cord lesion load, suggesting that NODDI may reflect clinically meaningful alterations in the WM independently of visible lesions.

Secondly, the length of the protocol does not allow the use of NODDI in routine clinical practice. However, changes in scanner hardware and acquisition protocols may lead to faster acquisition time, with the possibility of translating this technique from research centres to the clinical setting.

Finally, in the spinal cord, our relatively coarse resolution may have led to high levels of within-voxel partial volume effects, and the presence of highly anisotropic voxels may increase partial volume along the superior-inferior direction, thereby leading to higher values of ODI, as compared to brain WM areas with similar fibre organization.

Nonetheless, previous works^{7,12} have demonstrated that the echo times used in this study suffices to obtain an image quality suitable for group comparisons at the relatively low resolution employed here. Future work aiming at clinical translation is warranted to improve signal-to-noise and hence achieve a better resolution and mitigate partial volume effects.

In conclusion, the neurite integrity loss, which is a crucial element of neurodegeneration, occurs in both the brain and spinal cord WM in MS, but mainly when affecting the cervical cord, it may contribute to physical disability.

This raises the potential of using spinal cord NDI metric as a marker of disability in MS so that it can be used to assess the efficacy of neuroprotective treatments and to provide insights into the mechanisms of disability in MS.

	RRMS patients (N=28)	Healthy controls (N=20)	p-values
Age (years)	39.4 ± 6.6	36.6 ± 12.5	0.21
Gender (female:male; % female)	23:5 (82)	13:7 (65)	0.17
Disease duration (years)	8 ± 5.6	-	-
DMDs (N, %)	15 (54)	-	-
Brain GM volume (ml)	624.7 ± 41.1	705.6 ± 80.8	0.001^a
Brain WM volume (ml)	422 ± 33.9	482.7 ± 80.7	0.012^a
BPF	0.7 ± 0.02	0.8 ± 0.01	<0.0001^a

Spinal cord CSA (mm²)	75.8 ± 6.7	83.6 ± 8.7	0.009^a
Brain WM T2 lesion volume (ml) (median, range)	11.3 (0.3-41.3)	-	
WM spinal cord lesion count (median, range)	2 (0-8)		

^a linear regression model correcting for age and gender.

Note. Data are means ± standard deviation, unless otherwise indicated.

Abbreviations: RRMS: relapsing-remitting multiple sclerosis; DMDs: disease modifying drugs; GM: grey matter; BPF brain parenchymal fraction; CSA: cross-sectional area; WM: white matter

Table 3: Disability scales and cognitive tests in relapsing-remitting multiple sclerosis patients and healthy controls.

	RRMS patients (N=28)	Healthy controls (N=20)	p-value^a
EDSS (median, range)	2.5 (1-6.5)		
HADS Anxiety (median, range)	4 (0-21)		
HADS Depression (median, range)	3 (0-10)		
Mean 9-HPT (sec.)	23 ± 5.3	18.4 ± 5.1	0.006
T25FW (sec.)	5.8 ± 3.1	3.9 ± 0.5	0.03
PASAT	38.8 ± 16	48.6 ± 9.4	0.053
MSFC (z-score ^b)	0.03 ± 0.6	0.42 ± 0.4	0.016
SDMT	54.56 ± 11.2	62.13 ± 10.2	0.027
BVMT-R	22.28 ± 7.5	28.29 ± 39	0.002
CVLT-II	57.80 ± 11.3	63.27 ± 8.2	0.016

^a A linear regression model was used adjusting for age and sex.

^b Z-scores were computed according to the National MS Society's Clinical Outcomes Assessment Task Force indications using as a reference population our healthy control cohort.

Note. Data are means \pm standard deviation, unless otherwise indicated.

Abbreviations: RRMS: Relapsing-Remitting Multiple Sclerosis; 9-HPT: 9-hole Peg Test; T25FW: timed 25-foot walk; PASAT: Paced Auditory Serial Addition Test; MSFC: Multiple Sclerosis Functional Composite; SDMT: Symbol Digit Modality Test; BVMT-R: Brief Visuospatial Memory Test-Revised; CVLT-II Californian Verbal Learning Test II.

Table 4: NODDI measures in relapsing-remitting multiple sclerosis patients and healthy controls.

NODDI metric	RRMS patients	Healthy controls	Standardize d B coefficient (β)	P-value^a
Brain				
N of subjects	24	16		
NDI WM	0.57 \pm 0.03	0.60 \pm 0.03	-0.35	0.032
ODI WM	0.27 \pm 0.02	0.27 \pm 0.02	0.02	0.60
NDI GM	0.44 \pm 0.02	0.44 \pm 0.01	-0.25	0.24
ODI GM	0.47 \pm 0.01	0.47 \pm 0.01	0.22	0.73
Spinal cord				
N of subjects	27	18		
NDI Whole WM	0.52 \pm 0.07	0.58 \pm 0.06	-0.45	0.015
NDI Lateral WM	0.53 \pm 0.07	0.58 \pm 0.06	-0.38	0.021

(N voxels in the mask 134±47)				
NDI Dorsal WM (N voxels in the mask 106±28)	0.52 ±0.09	0.59 ±0.06	-0.38	0.020
NDI Ventral WM (N voxels in the mask 47±19)	0.48 ±0.09	0.55 ±0.07	-0.27	0.095
ODI Whole WM	0.16 ±0.05	0.19 ±0.04	-0.28	0.12
ODI Lateral WM (N voxels in the mask 134±47)	0.16±0.06	0.18 ±0.04	-0.15	0.4

ODI Dorsal WM (N voxels in the mask 106±28)	0.14 ±0.05	0.18 ±0.04	-0.39	0.024
ODI Ventral WM (N voxels in the mask 47±19)	0.19±0.07	0.21±0.05	-0.21	0.23
NDI GM (N voxels in the mask 190±26)	0.46 ± 0.06	0.49 ± 0.04	-0.20	0.20
ODI GM (N voxels in the mask 190±26)	0.09 ±0.04	0.1 ±0.03	-0.07	0.97

^a A linear regression model was used adjusting for age, sex and specific tissue volumes (brain) or cervical cord cross-sectional area (spinal cord).

Note. Data are means \pm standard deviations. *Abbreviations:* RRMS: relapsing-remitting multiple sclerosis; NDI: neurite dispersion index; ODI: orientation dispersion index; WM: white matter; GM: grey matter.

Table 5. Associations of NODDI metrics with clinical outcomes (a) and Expanded Disability Status Scale (b)

a)

Dependent variable	Independent variable	Standardized B coefficient	p-value
BRAIN			
MSFC	NDI WM	-0.09	0.56
CVLT-II	NDI WM	-0.12	0.51
BVMT-R	NDI WM	-0.1	0.56
SDMT	NDI WM	0.04	0.82
MSFC	Brain lesion volume	-0.42	0.06
CVLT-II	Brain lesion volume	-0.1	0.6
BVMT-R	Brain lesion volume	-0.09	0.68
SDMT	Brain lesion volume	-0.17	0.4
MSFC	BPF	0.53	0.034
CVLT-II	BPF	0.28	0.49
BVMT-R	BPF	0.33	0.28
SDMT	BPF	0.28	0.25
SPINAL CORD			
MSFC	NDI Whole WM	0.26	0.25
MSFC	NDI Lateral WM	0.17	0.46
MSFC	NDI Dorsal WM	0.23	0.30
MSFC	NDI Dorsal WM	0.23	0.27
MSFC	CSA	0.20	0.39

b)

Dependent variable	Independent variable	r _s coefficient	p-value
BRAIN			
EDSS	NDI WM	-0.14	0.51
SPINAL CORD			

EDSS	NDI Whole WM	-0.46	0.015
EDSS	NDI Lateral WM	-0.30	0.13
EDSS	NDI Dorsal WM	-0.48	0.012
EDSS	ODI Dorsal WM	-0.39	0.045
EDSS	CSA	-0.19	0.4
EDSS	SC lesion count	0.48	0.018
MSFC	SC lesion count	-0.27	0.17

a) Results are from linear regression models adjusted for age and sex.

Abbreviations: MSFC: Multiple Sclerosis Functional Composite; CVLT-II: California Verbal Learning Test-II; BVMT-R: Brief Visuospatial Memory Test-Revised; SDMT: Symbol Digit Modality Test; NDI: Neurite Density Index; WM: White Matter; BPF: brain parenchymal fraction; CSA: cervical cord cross-sectional area; SC: spinal cord.

b) Results are from Spearman's correlation test. As EDSS was correlated with the NDI in the spinal cord, associations between EDSS and measure of spinal cord atrophy and lesion load were assessed.

Abbreviations: EDSS: Expanded Disability Status Scale; NDI: Neurite Density Index; WM: White Matter.

Table 6. Associations between NODDI metrics in the brain and spinal cord and associations with atrophy measures (a) and lesion load (b)

a)

Dependent variable	Independent variable	Standardized B coefficient	p-value
NDI WM Brain	BPF	0.32	0.26
NDI WM Spine	CSA	0.30	0.19
NDI WM Brain	NDI WM Spine	0.04	0.84

b)

Dependent variable	Independent variable	r_s coefficient	p-value
NDI WM Brain	Brain lesion volume	-0.52	0.009
NDI WM Spine	SC lesion count	-0.33	0.10

a) Results are from linear regression models adjusted for age and gender. Abbreviations: NDI: Neurite Density Index; WM: White Matter; BPF: brain parenchymal fraction; CSA: cervical cord cross-sectional area.

b) Results are from Spearman's correlation test.

Abbreviations: NDI: Neurite Density Index; WM: White Matter; SC: spinal cord.

Figure 1. Example of NODDI maps

A) Example of brain NODDI maps from one healthy control (top row) and two patients: patient 1 (age 51, EDSS 3) and patient 2 (age 42, EDSS 3.5).

The first column shows the corresponding T2 weighed images and the lesion masks drawn for the two patients. The right panel shows the NODDI metrics: neurite density index (NDI) and orientation dispersion index (ODI). Visually, there is a reduction in NDI in MS lesions compared to the normal-appearing white matter in the two patients, and there are evident reduced NDI in the normal-appearing white matter of the two patients when compared to the healthy control.

B) Example of spine NODDI maps obtained from the same subjects. The first column shows the non-diffusion weighted image derived from the DWI. The right panel shows the NODDI metrics. Visually, there is a reduction in NDI in the white matter of the two patients when compared to the healthy control.

Figure 2. Boxplots of the NODDI metrics showing differences between patients and healthy controls.

Top: Neurite density index (NDI) values in the brain normal-appearing white matter of multiple sclerosis patients compared to healthy controls.

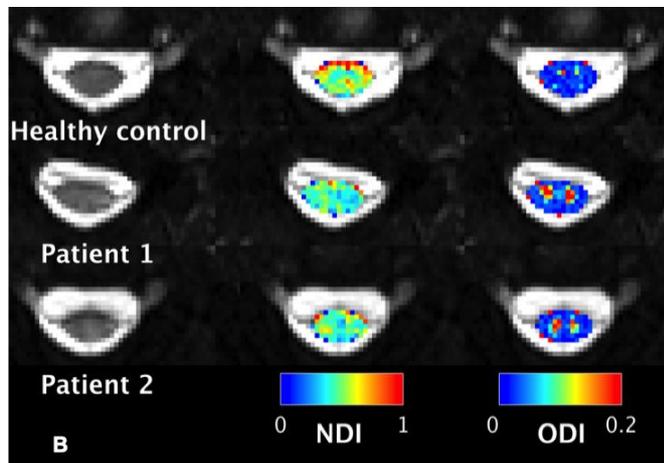

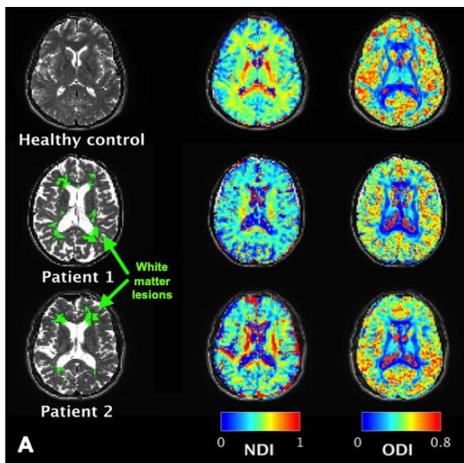

*p-value<0.05

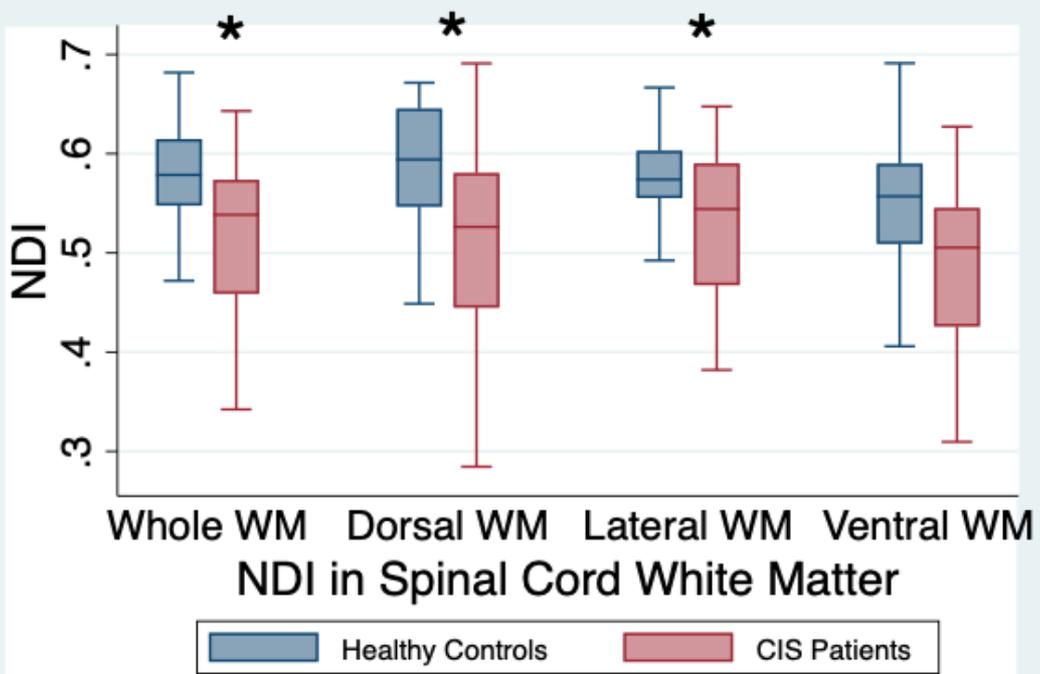

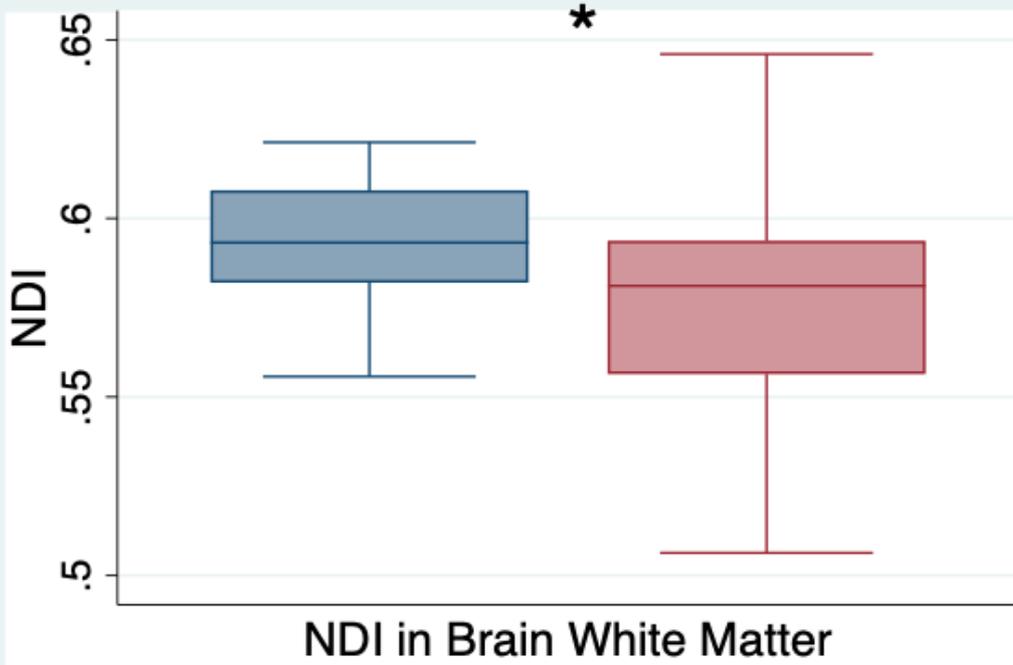

Bottom: Neurite density index (NDI) values in the spinal cord white matter of multiple sclerosis patients compared to healthy controls. *p-values<0.05
Abbreviations: NDI: neurite density index; WM: white matter; MS: multiple sclerosis

Figure 3. Relationship between the EDSS and the neurite density index (NDI) in the spinal cord white matter in relapsing-remitting MS patients (scatterplot).

Data are shown with confidence intervals computed the standard error of forecast due to the non-parametric variable. In relapsing-remitting MS patients the EDSS score was correlated a lower neurite density (NDI) in the spinal cord white matter ($r_s=-0.46$ $p=0.015$).

Abbreviations: EDSS: Expanded Disability Status Scale; NDI: neurite density index; WM: white matter.
