

1 Experimental methods

Trans ortho-, meta- and para-coumaric acid (hereafter referred to as *oCA*, *mCA* and *pCA*) were purchased from Aldrich and used without further purification.

The experimental setup has been described before.^[1-3] Briefly, deprotonated chromophore anions were generated by electrospray ionisation of solutions of the coumaric acids dissolved in MeOH with a few drops of NH₃, mass-selected by a quadrupole and guided into a hexapole trap. The anions were released from the trap at a rate of 20 Hz and focussed into the photoionization region of a collinear velocity-map imaging (VMI) spectrometer where they were intersected by nanosecond laser pulses with $\lambda = 364 - 315$ nm and energy ~ 5 mJ, generated by frequency-doubling the output of a Nd:YAG pumped dye laser. Electrons were accelerated towards a gated, position-sensitive detector where they were imaged using a CCD (charge-coupled device) camera. Laser-only images were subtracted from images recorded following the interaction of the laser light with the anions, to eliminate background counts arising from scattered laser light. The resulting photoelectron images were processed using the pBasex method.^[4] The VMI spectrometer was calibrated by recording the photoelectron spectrum of I⁻ and has a resolution of $\sim 5\%$.

2 Deprotonation site

In a combined action spectroscopy computation study, Rocha-Rinza and coworkers sought to determine whether *pCA*⁻ was deprotonated at the phenol group or carboxylic acid group, when generated by electrospray ionisation.^[5] The two p*K*_a values for *pCA*⁻ in aqueous solution are around 4.4 and 9.0 for deprotonation at the carboxylic acid and phenol groups, respectively, indicating that deprotonation occurs at the carboxylic acid group in aqueous solution. Rocha-Rinza and coworkers found identical action spectra for *pCA*⁻ and methyl-substituted derivatives, but analysis of the photodissociation pathways led to the conclusion that the chromophore was formed in its phenoxide form. A separate theoretical study concluded that the maxima in the experimental action spectra were consistent with the calculated vertical excitation energy of the first $\pi \rightarrow \pi^*$ transition in the phenoxide form of *pCA*⁻ (3.0 eV).^[6] The VDE measurements we report in this paper support the conclusion that coumaric acids are formed in their phenolate forms during the electrospray ionisation process.

3 Computational methods and results

The geometric and electronic structures of the molecules were calculated using the Gaussian09 suite of programmes.^[7] The geometric structures of the phenolate (O^-) and carboxylate (COO^-) forms of the deprotonated coumaric acid chromophores, and corresponding neutral radicals, were optimised using the B3LYP hybrid functional^[8–11] and the aug-cc-pVTZ basis set.^[12–17] Frequency calculations were performed to confirm that minima in the potential energy surface were reached.

Vertical detachment energies (VDEs) were determined using the electron propagator theory (EPT) method with the outer valence Green's function (OVGF)^[18,19] propagator and a 6-311++G(3df,3pd) basis set.^[20–22] We have already benchmarked this approach against the high-resolution photoelectron spectrum of the phenoxide anion and shown that it yields good results for the deprotonated green fluorescent protein chromophore anion.^[3] Moreover, the maximum in the 364 nm (3.41 eV) photoelectron spectrum of *p*CA⁻ (2.9 – 3.0 eV) (Fig. 2 in the main text) is in good agreement with our calculated VDE for the phenolate form of *p*CA⁻ (3.0 eV) and with calculations carried out by Zuev *et al.* for *p*CA⁻ (2.92 eV)^[6] and Gromov *et al.* for the deprotonated methyl-4-hydroxycinnamate thio ester analogue (2.90 eV)^[23] and the experimental VDE reported for the methyl coumarate chromophore anion.^[24]

Vertical excitation energies (VEEs) of the singlet excited electronic states of the phenolate deprotonated coumaric acid chromophores were calculated using the CAM-B3LYP/6-311++G(3df,3pd) method. The long-range corrected version of B3LYP using the Coulomb Attenuating Method (CAM)^[25] was chosen for its potential to describe excited states with charge-transfer character and because it has been shown to yield reasonably good results for the phenolate form of the *p*CA⁻ anion.^[26] Our VEEs are similar to those calculated for the analogous methyl coumarates^[26] and are consistent with action spectra of the methyl coumarates.^[26] Our value for *p*CA⁻ lies within the range of VEEs calculated by Zuev *et al.*^[6] and Uppsten and Durbeej^[27].

VDEs to the lowest lying electronically excited states of the neutral radicals, D₁, were determined by first calculating the D₁–D₀ VEEs at the optimised geometries of the anions and adding these values to the calculated VDEs (Table S8), giving values of 4.219, 3.887, 3.885 and 4.392 eV for *o*CA⁻, *s-trans* *m*CA⁻, *s-cis* *m*CA⁻ and *p*CA⁻, respectively.

Photoelectron spectra of phenolate deprotonated coumaric acid chromophores were calcu-

lated using ezSpectrum 3.0.^[28] These calculations require the equilibrium geometries, harmonic frequencies and normal mode vectors of the deprotonated coumaric acid anions and corresponding neutral radicals as input and these were obtained from the B3LYP/aug-cc-pVTZ calculations performed using Gaussian09. The Franck-Condon overlap integrals were calculated in ezSpectrum using the parallel normal mode approximation. The vibrational temperature of the anions was assumed to be 300 K and the minimum intensity threshold was set to 0.001. The maximum number of vibrational quanta in the anion and radical were limited to 4 and 6, respectively, and the vibrational energy in the anion state was capped at 0.3 eV. The resulting stick spectra were convoluted with instrumental profiles with HWHM in the range 10 – 21 meV, corresponding to 5% eKE resolution at the 0-0 transition.

VDEs, VEEs and oscillator strengths plotted in Fig. 2 of the paper for $m\text{CA}^-$ are the averages of those for the *s-cis* and *s-trans* forms.

Table S1: Z-matrix of the B3LYP/aug-cc-pVTZ optimised geometries used to calculate the VDE, VEEs and FC spectra for the phenolate form of $o\text{CA}^-$, $\phi_a = 0^\circ$.
