Highlights:

Based on morphological and genetic characteristics, we describe a new species of hoolock gibbon (*Hoolock tianxing*) that is distributed between the Irrawaddy-Nmai Hka Rivers and the Salween River, which is previously assigned to *H. leuconedys*.

Abstract:

We describe a species of *Hoolock* gibbon (Primates: Hylobatidae) that is new to science from eastern Myanmar and southwestern China. The genus of hoolock gibbons comprises two previously described living species, the western (*Hoolock hoolock*) and eastern hoolock (*H. leuconedys*) gibbons, geographically isolated by the Chindwin River. We assessed the morphological and genetic characteristics of wild animals and museum specimens, and conducted multi-disciplinary analyses using mitochondrial genomic sequences, external morphology, and craniodental characters to evaluate the taxonomic status of the hoolock population in China. The results suggest that hoolocks distributed to the east of the Irrawaddy-Nmai Hka Rivers, which are previously assigned to *H. leuconedys*, are morphologically and genetically distinct from those to the west of the river, and should be recognized as a new species, the Gaoligong hoolock gibbon or skywalker hoolock gibbon (***Hoolock tianxing* sp. nov.**). We consider that the new species should be categorized as Endangered under IUCN criteria. The discovery of the new species focuses attention on the need for improved conservation of small apes, many of which are in danger of extinction in southern China and Southeast Asia.

Keywords: New species, *Hoolock tianxing*, gibbon, Mt. Gaoligong, endangered species

Introduction

Gibbons and siamangs (Hylobatidae) are small apes inhabiting southern, eastern and Southeast Asia. Currently, four genera (*Hoolock*, *Hylobates*, *Nomascus* and *Symphalangus*) and up to 19 living species are recognized [Mittermeier et al., 2013]. Hoolock gibbons, or hoolocks, occur in the northwestern part of modern-day gibbon distribution in mainland Asia, with populations in India, Bangladesh, Myanmar and China (**Fig 1**). They differ from other gibbon genera in a series of morphological [Mittermeier et al., 2013], acoustic [Geissmann, 2002] and chromosomal [Müller et al., 2003] characteristics. The most evident morphological characteristic of hoolocks is their conspicuous white brow [Choudhury, 2013; Mittermeier et al., 2013], which is the source of their other common name, the white-browed gibbons.

Hoolocks were first described scientifically by Harlan [1834] under the name *Simia hoolock*. They were subsequently transferred to *Hylobates*, and then assigned to their own distinct subgenus (later elevated to genus), first *Bunopithecus* [later restricted to an extinct Quaternary gibbon from China; Groves, 2001; Prouty et al., 1983] and then *Hoolock* [Mootnick & Groves, 2005]. Taxonomic variation between hoolock populations was first recognized by Groves [1967], who identified a major east-west morphological division and established the subspecies *Hylobates hoolock leuconedys* to distinguish eastern hoolock populations from their western counterparts. These two groups were interpreted as subspecies for 40 years [Brandon-Jones et al., 2004; Groves, 1967], but are now recognized as distinct species, the western hoolock (*Hoolock hoolock*) and the eastern hoolock (*H. leuconedys*) [Geissmann, 2007; Groves, 2001;

Mittermeier et al., 2013; Thinh et al., 2010a]. More recently, new hoolock populations found between the Lohit and Dibang Rivers in Assam and Arunachal Pradesh [Chetry et al., 2008, 2010; Chetry & Chetry, 2010; Das et al., 2006] have been described as a new subspecies of western hoolock, the Mishmi Hills hoolock (*H. hoolock mishmiensis*) [Choudhury, 2013].

These different groups of *Hoolock* can be distinguished on the basis of external morphological characteristics (**Fig 2**); notably, the shape of the eyebrows and the color of the eye rings, beard, and preputial tuft [Choudhury, 2013; Groves, 1967; Groves, 1972]. In *H. hoolock*, adult males are jet black with a black or faintly grizzled preputial tuft, closely spaced white brow streaks connected by white hair, and white hair on the chin or below the eyes, while females are buffy colored, the color of hands and feet being the same as the body [Groves, 1967, 1972, 2001]. In *H. leuconedys*, adult males have a black coat with a white preputial tuft and well-separated brow streaks, and adult females have again a buffy pelage but with distinctly lighter brown hands and feet [Das et al., 2006; Groves, 1972]. Adult males of *H. h. mishmiensis* differ from those of *H. h. hoolock* in having thick, closely connected eyebrows, a prominent black or greyish beard tuft, and a buffy or rufescent buff genital tuft; Choudhury [2013] also noted some slight differences in the white face ring of *H. h. mishmiensis* females, with the brows of this subspecies being transversely oriented above the orbital ridge, whereas they are slightly concave in *H. h. hoolock* and sharply downcurved in *H. leuconedys*. This series of external characters was used to identify *H. h. mishmiensis* as a new subspecies, and may therefore be helpful for assessing the taxonomic status of other little-studied

hoolock populations.

Large rivers are considered to represent barriers for gibbon dispersal [Groves, 1967; Thinh et al., 2010b], not only because these primates do not swim and are largely restricted to the forest canopy, but also because forested environments in river valleys are generally unfavorable for gibbons [Groves, 1967; Thinh et al., 2010b]. The Chindwin River in Myanmar was identified as the distributional boundary between *H. hoolock* and *H. leuconedys* [Groves, 1967], and the Lohit River may also act as a boundary between *H. h. hoolock* and *H. h. mishmiensis* [Choudhury, 2013]. Large rivers may have played therefore an important role in the diversification and speciation of hoolocks and other hylobatids [Groves, 1967; Thinh et al., 2010b], and the taxonomic status of other hoolock populations that are isolated by large rivers needs to be critically assessed.

Mt. Gaoligong (or Gaoligongshan) is located between the Salween River (Nujiang in Chinese, Mae Nam Salawin in Thai, and Thanlwin in Burmese) and the Nmai Hka tributary of the Irrawaddy River in western Yunnan Province, China, and eastern Myanmar [Chaplin, 2005], and represents the easternmost end of the distribution of hoolock populations (**Fig. 1**). Hoolocks were first recorded from Mt. Gaoligong by the American Museum of Natural History's Asiatic Zoological Expedition in 1917 [Anonymous, 1917] **(Fig S1)**, and gibbon specimens collected by the expedition from this region are now in the American Museum of Natural History (New York) and the Museum of Comparative Zoology (Harvard University, Cambridge, Massachusetts). More recently, hoolocks on Mt. Gaoligong have been the focus of extensive field

research by PFF and his team [Fan, 2016; Fan et al., 2011, 2013]. These gibbons were originally identified as *H. leuconedys* [Groves, 1967, 2001]. However, during long-term observations of wild individuals, PFF noticed that their external morphological characteristics differ from the typical morphology of *H. leuconedys*, which had been originally described by Groves [1967] on the basis of individuals located east of the Chindwin River.

Based on the observed morphology of hoolock individuals from Mt. Gaoligong, and the allopatric separation of this population from other hoolock populations by a large river system, we hypothesized that the population may represent a distinct, undescribed hoolock taxon. To test this hypothesis, we collected photographs and feces from both wild and captive individuals, examined museum specimens, and conducted multidisciplinary analyses using both DNA and morphological/morphometric data. Based on the results of this integrative study, we conclude that the Mt. Gaoligong population represents a new species of hoolock gibbon.

Methods

Live animals

Intensive wild hoolock population surveys were conducted in Mt. Gaoligong, Yunnan, in 2008 and 2009 [Fan et al., 2011], with photographs taken of individuals in two family groups at Lamahe and Xiangbai (**Table S1**). Further long-term ecological studies were then conducted on hoolocks at Datang [three groups, 10 months; Zhang et

al., 2011], Nankang [one group and one solitary female, 15 months; Fan et al., 2013], Banchang [three groups, 46 months; Yin et al., 2016], and Xiangbai [two groups, one month; Chang-Yong Ma, unpublished data]. One group (NA) and the solitary female (NB) at Nankang and one group (BB) at Banchang were habituated to researchers during these ecological studies, and photographs were taken of 14 habituated and unhabituated individuals. We also visited Dehong Wildlife Rescue Center (Mangshi County, Yunnan, May 2015), Yunnan Safari Park (Kunming, Yunnan, June 2013 and October 2014), Taibao Park (Baoshan, Yunnan, May 2015), three zoos (Kunming, October 2015; Zhengzhou, August 2015; Beijing, September 2015), and Pianma Ranger Station of Gaoligongshan National Nature Reserve (Nujiang, Yunnan, October 2015), which contained captive hoolock individuals, as well as a hoolock kept as a pet in Dulujiang, Nujiang County, Yunnan; we obtained photographs of 22 captive individuals (**Table S1**).

Morphological and morphometric analyses

We examined 122 hoolock specimens curated at: the American Museum of Natural History (AMNH), New York (n = 86); the Academy of Natural Sciences of Philadelphia (ANSP), Philadelphia (n = 1); the National Museum of Natural History (USNM), Smithsonian Institution, Washington, D.C. (n = 3); the Museum of Comparative Zoology (MCZ), Harvard University, Cambridge, Massachusetts (n = 2); the Natural History Museum (NHM), London (n = 21); the National Zoological Museum of China, Institute of Zoology (IOZ), Chinese Academy of Sciences, Beijing (n = 3); and the Kunming Natural History Museum of Zoology (KNHMZ), Kunming Institute of

Zoology (KIZ), Kunming (n = 6), representing historical specimens collected from Mt. Gaoligong as well as specimens attributed to both *H. hoolock* and *H. leuconedys* (**Table S2**). Specimens were identified following Groves [1967].

Twenty-three craniomandibular variables were measured from 77 adult hoolock individuals in AMNH, ANSP, MCZ, NHM and USNM by CG (Table S3). The provenance and measurements of all specimens are given in **Table S2**. Morphometric variation was analyzed using principal component analyses (PCA) and discriminant function analyses (DFA) in SPSS v17.0 (SPSS Inc, Chicago, Illinois), conducted on log10-transformed variables. For the DFAs, specimens of *H. hoolock* were assigned to their own group, and specimens of *H. leuconedys* from the west and the east of the Irrawady-Nmai Hka River were assigned to two groups based on their provenance and morphological and molecular differentiation (see below).

Taxonomic differences of the hoolock dentition were investigated using discrete morphological traits and geometric morphometrics (GM). Cusp nomenclature follows Swindler [2002]. Special attention was paid to the lower P4 and the upper and lower molars, given their usefulness in hominoid alpha taxonomy [Bailey & Lynch, 2005; Frisch, 1965; Kitahara-Frisch, 1973; Martinon-Torres et al., 2006; Ortiz et al., 2015; Swindler, 2002; Uchida, 1996b]. Although we conducted GM analyses for all upper and lower molar types, we only present here the results of the M2s due to their reduced degree of dental wear (vs. M1s) and relatively large samples in museum collections. All photographs for GM analysis were taken by AO following Ortiz et al. [2015]. We used tpsDig2 v2.22 [Rohlf, 2015] to place 10 and 11 semilandmarks representing the

outline of each upper and lower molar, respectively. Shape information was extracted using a Procrustes superimposition, as implemented in MorphoJ v1.06d [Klingenberg, 2011]. Multivariate statistics (PCA and DFA) were implemented in MorphoJ v1.06d and SPSS v17.0.

Molecular analyses

We obtained three recent hoolock soft tissue samples (one piece of muscle and two small pieces of pedal skin) from three different individuals housed at KIZ, as well as 25 fecal samples obtained from Chinese captive individuals, confiscated wild individuals, and wild individuals from two field localities in Mt. Gaoligong (**Table S1**). These specimens represented individuals identified as *H. leuconedys* sensu stricto, and the Mt. Gaoligong hoolock population based on locality data and morphological characteristics. We also obtained one sample of *H. hoolock* from Dhaka Zoo, Bangladesh. Museum specimens were treated in a series of 24-hour washes in 75%, 50%, and 25% ethanol, followed by successive 24-hour immersions in ddH_2O. The fecal samples were collected using a 'two-step' storage procedure following Nsubuga et al. [2004], and were preserved at -20°C after arrival in the laboratory. DNA was extracted from recent and historical tissue samples using a DNeasy blood and tissue kit (QIAGEN, Hilden, Germany). Fecal DNA was extracted using a QIAamp® stool mini kit (QIAGEN, Hilden, Germany).

We first amplified and sequenced two mitochondrial gene regions, the cytochrome *b* (*CYT B*) and D-loop regions (**Table S4**), for all 27 samples (**Table S1**). Based on the

genetic diversity in our samples and preliminary phylogenetic analysis, we selected a subset of samples for whole mitochondrial genome (hereafter mitogenome) sequencing using either Sanger or next-generation sequencing (NGS). The mitogenomes of one *H. hoolock* (HHO) and one *H. leuconedys* (BSJO) were amplified using 19 pairs of primers (**Table S4**) via individual PCRs. These PCR amplicons were 0.9-1.4 kb in length and overlapped in 100-500 bp. PCR amplicons were gel-purified and were sequenced on an ABI3130*xl* sequencer using the BigDye Terminator Cycle Sequencing Kit (Applied Biosystems). For the remaining samples, amplicon sequencing [O'Neill et al., 2013] and hybridization-capturing [Horn, 2012] were employed, accompanied by the NGS technique. We first amplified the complete mitogenome of the modern muscle tissue sample using long-range PCR [Chan et al., 2010] using two pairs of primers (**Table S4**). PCR products were used for NGS and for generating probes for capture-hybridization, following Horn [2012]. For amplicon sequencing, PCR products were sheared using an IonShear kit (ThermoFisher Scientific, USA), and ligated with adapters using Ion Plus Fragment Library and Ion Xpress Barcode Adapter kits (ThermoFisher Scientific, USA). PCR products were also used to generate homemade probes using a BioNick Labeling Kit (Invitrogen, USA). Stool DNA libraries were analyzed using the same Ion Xpress kits. Capture-hybridization was performed for each individual stool DNA library using the homemade probes and an Oligo aCGH Hybridization Kit (Agilent, USA), following Horn [2012]. Hybridization was performed in a Mastercycler nexus thermocycler (Eppendorf) at 65°C for 72 hours. Because our samples were all modern or relatively recently collected, we did not conduct a second run of enrichment, as

recommended for ancient DNA samples by Horn [2012]. After quantification using a Qubit Fluorometric Quantitation (ThermoFisher Scientific, USA), all libraries were pulled and sequenced using a 316 v2 chip with the Ion Torrent™ Personal Genome Machine® (PGM) system (ThermoFisher Scientific, USA).

The Sanger sequencing results were assembled and edited using Lasergene v7.1 and aligned using MUSCLE. Available *CYT B* sequences of gibbons in GenBank were downloaded and included in our analyses (**Table S1**). PGM results were initially analyzed and converted into FASTQ format using the Torrent Suite v4.0.2. Reads shorter than 60 bp were filtered and adapter sequences were trimmed. We de novo assembled the modern muscle tissue sample and mapped the reads to a hoolock mitogenome (NC_023377, withdrawn by the authors from GenBank; Atsushi Matsui personal communication) using Geneious v8.1. Reads generated for each fecal sample were mapped to NC_023377 and the assembly muscle tissue mitogenome. To control for contamination, we compared the *CYT B* and *D-loop* sequences generated by NGS and Sanger sequencing from the same samples; we considered mismatches of no more than 1 bp as indicating no contamination. Mitogenomes were aligned using MUSCLE and annotated using Geneious v8.1. We checked premature stop codons in each coding gene to avoid potential inclusion of pseudogenes. We also downloaded 20 mitogenomes representing 10 gibbon species, two gorilla species, two chimpanzee species, two orangutan species, three macaque species, and humans from GenBank for inclusion in analyses (**Table S1**).

Phylogenetic analyses

Phylogenetic analyses were performed using RAxML for maximum likelihood tree estimation, and BEAST v1.8 for Bayesian tree and divergence time estimation. We first analyzed a dataset comprising 31 complete or nearly complete mitogenomes, including 11 newly derived and 20 from GenBank. All tRNAs, the ND6 gene and the D-loop region were removed from the dataset alignment. The remaining 13,375 bp alignment, including all other coding genes and two rRNA genes, was subdivided into 38 data blocks based on gene and codon positions. Best-fit partitioning schemes and evolutionary models were determined simultaneously using PartitionFinder v1.0 [Lanfear et al., 2012] under the Bayesian Information Criterion (BIC).

Although gibbons are present in the fossil record, it has been extremely difficult to determine the relationships of these extinct taxa with living species and whether they represent crown-group or stem-group gibbons [Benton et al., 2015]. We therefore selected fossil primates with well-accepted phylogenetic relationships to calibrate the tree. To calibrate the root of the tree (crown Catarrhini), we used *Rukwapithecus fleaglei* from the Miocene Nsungwe Formation of Tanzania, which has been identified as the oldest stem hominoid and crown catarrhine yet known [Stevens et al., 2013]. The minimum date for this fossil is 24.44 million years ago (Ma) based on the age of the Nsungwe Formation [Roberts et al., 2010]. Using a uniform distribution for this calibration, we set the lower boundary to 24.44 Ma. We set the upper boundary to 34 Ma at the Eocene-Oligocene transition [Seiffert, 2006] following Benton et al. [2015]. To calibrate the crown Hominoidea, we used *Sivapithecus indicus* from the Miocene Chinji Formation of Pakistan [Kappelman et al., 1991], which has been identified as a

member of the Ponginae [Seiffert, 2006]. The youngest estimated date for this fossil is 11.6 Ma based on the age of the Chinji Formation [Kappelman et al., 1991]. Using an exponential distribution for this calibration, we set the lower boundary to 11.6 Ma with a mean value of 7.45, to allow the upper soft boundary to extend to the Eocene-Oligocene transition. The second calibration used the most recent common ancestor (MRCA) of humans and chimpanzees. *Sahelanthropus tchadensis* from Toros Menalla, northern Chad [Brunet et al., 2002] is currently interpreted as likely to represent the oldest crown-group hominin post-dating the human-chimpanzee split [Strait, 2013]. The youngest date for this fossil is 6.5 Ma according to the relative chronology of the Nawata Formation [Deino et al., 2002]. Given that fossils dated between 7–10 Ma from the tribe Hominini are scarce and difficult to allocate to lower taxonomic categories, we used 10 Ma as the soft upper boundary [Benton et al., 2015]. We used an exponential distribution for this calibration and set the lower boundary to 6.5 Ma with a mean value of 1.2 to allow the upper boundary to extend back to 10 Ma. The alignment was divided into seven partitions (**Table S5**) according to the results of PartitionFinder. Each BEAST analysis employed seven lognormal relaxed-clock models (i.e., one per partition), a birth–death tree prior, and was run for 40 million generations, sampling every 4,000 generations. Posterior distributions and effective sample sizes (ESSs) were calculated using Tracer v1.6.

We also analyzed a dataset including ~1823 bp partial *CYT B* and D-loop regions for an extended sampling of 34 hoolocks including those retrieved from GenBank (**Table S1**) in order to test whether the external morphological pattern we observed is

298 also supported by molecular data. The partition scheme and evolutionary models were
299 also estimated using PartitionFinder (**Table S5**). We used an extensive Bayesian skyline
300 tree prior.

301 Except for historical specimens, no gibbon was killed or captured during this
302 research. All field research reported in this manuscript was permitted by the
303 Management Bureau of Gaoligongshan National Nature Reserve, and adhered to the
304 legal requirements of China and the American Society of Primatologists' principles for
305 the ethical treatment of nonhuman primates.

306

307 **Results**

308 **External morphology**

309 All black hoolock individuals from Mt. Gaoligong have white eyebrows, which is
310 a distinctive feature of the genus. However, they differ from the holotype of *H.*
311 *leuconedys* (NHM ZD.1950.391) in four characteristics: i) the eyebrow streaks are
312 thinner and separated by a large gap; ii) the beards are completely black or brown
313 instead of white; iii) white hair is absent in the suborbital area; iv) the genital tufts are
314 black, brown or dark gray instead of whitish (**Table 1; Fig 3; Fig 2*c,d*; Fig S2**). Adult
315 females from Mt. Gaoligong are characterized by incomplete white face rings, with
316 only sparse white hairs present on the lateral orbital and suborbital regions (n=7; **Fig**
317 **2*h***), which are much less conspicuous than those of typical *H. leuconedys* females (n=7;
318 **Fig 2*g***). We also found geographic variation among *H. leuconedys* specimens from east

and west of the Irrawaddy River. Consistent with the holotype of *H. leuconedys*, all individuals from the west of the river display thick eyebrows, a white or silvery genital tuft in males, and whitish hair around the orbital and suborbital regions in females. In contrast, males from the east of the Irrawaddy River (MCZ 26474, 30383; AMNH M-43068; NHM ZD.1933.7.29.15) resemble Mt. Gaoligong hoolocks in displaying thin, well-separated eyebrows and a dark genital tuft, as well as in lacking white hair in the suborbital area and lacking a white beard. The genital tuft of two old adult males (identified from their heavily worn lower molars) from this region (MCZ 30383 and IOZ 25965, Fig S3) is gray in color, paler than individuals from Mt. Gaoligong but still much darker than that of NHM ZD.1933.7.29.15. Although female hoolocks from this region (e.g., AMNH M-43065; USNM 257988) exhibit whitish hair on the suborbital regions, it is less conspicuous or absent lateral to the orbits.

Craniodental variation

Results of the PCA using 23 craniodental variables indicate that the first principal component (PC1) accounts for 40.30% of the variance and is positively correlated with all variables (loading > 0.24) except for the palate breadth at upper M2 (loading = 0.10), reflecting a size effect (**Table S3**). The second principal component (PC2) represents 10.23% of the variance and is dominated by the breadth at upper M2, the breadth at upper M3, and face height (loading > 0.52). The plot of the first two components revealed extensive overlap between specimens representing different species/allopatric populations (**Fig 4*a***). Similar patterns were observed when using the shape outline of upper and lower M2s (**Fig 4*c, e***). These results suggest that skull and tooth shape are

conserved among hoolock taxa, a general pattern observed in hylobatids [Jablonski and Chaplin, 2009]. **Fig4*b, d, f*** illustrate the scatter plots of the first two discriminants using the same craniodental dataset, showing that *H. hoolock* and *H. leuconedys* from east and west of the Irrawady River are more clearly separated from each other, although there is still some overlap between the three groups. The likelihood of individuals being correctly assigned to their own taxon/group ranges between 87% and 93% (**Table S6**).

The lower p4 shows patterns of morphological variation corresponding to the different hoolock species and geographic populations (**Fig 5**). The lower p4 of *H. hoolock* individuals from Myanmar is trapezoidal-shaped, and the talonid is generally wider than the trigonid because: i) the metaconid and protoconid are relatively small; ii) the hypoconid is generally present and equal in size to the entoconid; iii) both the entoconid and hypoconid are moderate or large in size. (**Fig 5a**). *H. hoolock* individuals from Assam, India, differ slightly from their counterparts from Myanmar in that the lower p4 is more square-shaped in overall outline because: i) the protoconid is well-developed; ii) the entoconid and hypoconid are present but not strongly developed; iii) the talonid and trigonid are similar in width (**Fig 5b**). In *H. leuconedys* individuals from the west of the Irrawaddy River, the lower p4 has a rhomboidal shape (**Fig 5c, *d***), and the trigonid is usually wider than the talonid because: i) the two mesial cusps are very large, with the metaconid being as large as the protoconid; ii) the hypoconid and entoconid are greatly reduced and in some cases absent (especially the hypocone). In hoolock individuals from the east of the Irrawaddy River, the lower p4 is generally oval-shaped because: i) the teeth are mesiodistally shorter; ii) the talonid and trigonid

363 are of equal width; iii) distal cusps are present, but not well-developed (**Fig 5*e, f***).

364 **Genetic variation**

365 We obtained partial *CYTB* and D-loop sequence data for all 27 soft tissue and fecal
366 samples (~1823 bp; 3.7% missing data). The two samples selected for mitogenome
367 sequencing using Sanger and twelve samples selected for NGS were all successfully
368 sequenced. We obtained 14,776 reads for the tissue DNA library, and 21,336–109,463
369 reads for the fecal DNA libraries. At least 95% of the amplicon sequencing reads could
370 be mapped to the hoolock mitogenome. Mean coverage (depth/site) of the modern
371 tissue samples was 248.1 (SD=126.7). Hybrid capture yielded mean coverages of 35.2–
372 222.5. Between 5.00% and 39.92% of the reads could be mapped to the reference
373 mitogenome. We obtained complete (or nearly complete; ≤0.5% missing data)
374 mitogenomes for nine individuals, and partial mitogenomes for the other three
375 individuals (5.5–16.6% missing data; **Table S7**).

376 The mitogenome gene tree is well-supported for all interspecific relationships
377 (posterior probabilities [PP] ≥0.98) except for the root of Hylobatidae **(Fig 6**).
378 *Hylobates* and *Symphalangus* are fully supported as sister groups (PP=1.0). The MRCA
379 of Hylobatidae is estimated as occurring 6.79 Ma (95% CI=7.64-6.01 Ma). The single
380 sample representing *H. hoolock* diverged from the other samples at ca. 1.14 Ma (PP=1.0;
381 95% CI=1.38-0.93). Two distinct clades are detected within samples previously
382 classified as *H. leuconedys* from both east and west of the Irrawaddy River (PP=1.0),
383 which diverged ca. 0.49 Ma (0.60-0.39 Ma).

In the gene tree based on partial mitochondrial hoolock sequence data, the primary division is between one sample of *H. h. hoolock* from Dhaka Zoo (Bangladesh) and all other samples (PP=1.0; **Fig 7**). It should be noted that all these other samples were identified as *H. leuconedys*, except for two individuals from GenBank, which were identified as *H. h. hoolock* (Y13304, Y13305). Two monophyletic clades are again strongly supported (namely clades I and II, PP≥0.97). All individuals in clade I, from various sources with known taxonomic identities, show typical *H. leuconedys* morphology. Clade II consists of all five wild individuals from Mt. Gaoligong, together with fecal or soft tissue samples from five other animals from Chinese museums and captive centers (**Table S1**). Except for the GenBank sequences of unknown identity, all wild-born captive individuals are morphologically similar to the Mt. Gaoligong population. The K2P distance of the complete *CYT B* dataset between the Bangladesh *H. hoolock* samples and *H. leuconedys* sensu lato was 2.9%, and the K2P distance between clades I and II was 1.2%.

Based on our examination of museum specimens and observation of wild animals, morphological and morphometric comparisons, and genetic analyses, we demonstrate that eastern hoolocks from the east of the Irrawaddy River are distinguishable according to a range of external and molecular characteristics from individuals from the west of the Irrawaddy River. We therefore recognize the hoolock population distributed to the east of the Irrawaddy River and to the west of the Salween River as a new species.

405 **Systematic Biology**

406 Order Primates Linnaeus, 1758

407 Family Hylobatidae Gray, 1870

408 Genus *Hoolock* Mootnick and Groves, 2005

409 *Hoolock tianxing* sp. nov.

410 *Hylobates hoolock leuconedys*: Groves, 1967: 276 (part).

411 Skywalker hoolock gibbon (天行长臂猿) or Gaoligong hoolock gibbon (高黎贡
412 白眉长臂猿).

413 **Holotype:** AMNH M-43068 (adult male, skin only; **Fig 3**), an adult male collected
414 by Roy Chapman Andrews and Yvette Borup Andrews on April 5, 1917 during the
415 American Museum of Natural History's Asiatic Zoological Expedition.

416 **Type locality:** Ho-mu-shu (=Hongmushu) Pass, Baoshan, Yunnan, China (25.00
417 N, 98.83 E).

418 **Paratypes:** AMNH M-43065 (adult female, skin only; **Fig S1**) and MCZ 26474
419 (=AMNH M-43067, skin and skull, relocated to MCZ in September 1930), collected at
420 the same locality as the holotype. IOZ 25965 (adult male, skin and skull; **Fig S3**),
421 collected on June 4, 1965 at Tengchong, Yunnan, China. MCZ 30383 (adult male, skin
422 and skull; **Fig S3**) collected on January 15, 1932, ca. 40 miles east of Bhamo, northern
423 Myamnar, during the Brooke Dolan expedition.

424 **Etymology**

425 *Tianxing* constitutes the pinyin (standard mainland Chinese phonetic alphabet)
426 transliteration of 天行, meaning heaven's movement or skywalker (*xing*, movement,
427 can act as either a noun or a verb), a name referring to the unique locomotory mode of
428 gibbons (brachiation; **Fig S4**) and derived from the text of the I Ching, an ancient
429 Chinese work of divination: 天行健君子以自强不息 ("As heaven's movement is
430 ever vigorous, so must the scholarly gentleman (君子, "*junzi*") ceaselessly strive for
431 self-improvement"). Gibbons were widely regarded as a symbol of scholar-officials or
432 *junzi* in ancient China, as the perceived "noble" characteristics of gibbons were
433 considered to accord with the aesthetic taste of both Daoism and traditional Chinese
434 scholars [van Gulik, 1967; Ye & Heule, 2013].

435 **Diagnosis**

436 *Hoolock tianxing* is a hoolock gibbon distinguished from other described hoolock
437 species by a combination of external and dental characters. In males, the ventral pelage
438 is brownish, resembling that of *H. leuconedys* but differing from *H. hoolock*. The
439 eyebrows are relatively thinner than in *H. hoolock* and *H. leuconedys*, and well-
440 separated, differing from the condition in *H. hoolock*, where there is only a narrow gap
441 between the eyebrows. White hairs are absent in the suborbital area, differing from *H.*
442 *leuconedys*, which has white hairs in the suborbital area. The beards of males are black
443 or brown, differing in color from *H. leuconedys*, which has a whitish or buffy beard,
444 and not as prominent as in *H. hoolock*. The black, brown or grayish genital tuft in males
445 differs in color from *H. leuconedys*, which has a white or silvery tuft. The face rings in
446 females are incomplete, differing from the condition in both *H. hoolock* and *H.*

447 *leuconedys*. The crown outline of the lower p4 is oval, making it distinct from *H.*
448 *leuconedys* and *H. hoolock* individuals from Myanmar and more similar to *H. hoolock*
449 from Assam.

450 **Description**

451 In adult males, the ventral pelage is generally dark brown, and the dorsal pelage
452 has a brownish overlay, especially apparent under bright light (**Fig S2**); eyebrows thin
453 and well-separated; white hairs absent in the suborbital area; beard not conspicuous,
454 black or brown in color, not contrasting with the color of the chest or body; genital tuft
455 prominent, usually black or dark brown in color with a few white hairs present, not
456 contrasting with the color of the groin. In older animals, the genital tuft is fainter and
457 light brownish in color (**Fig S5**). In adult females, pelage color is generally yellowish,
458 but varies with age (yellowish white to reddish blonde); eye rings incomplete; white
459 hair typically not present on the lateral orbital region, or if present, not as conspicuous
460 as on the brows on the lateral orbital region; white hair sometimes also not present on
461 the suborbital region (**Fig S6**). Juveniles do not have white hair on the chin or under the
462 eyes; eyebrows are not always well-separated. Lower p4 is generally mesiodistally
463 short and oval-shaped, with the talonid and trigonid of equal buccolingual width. Distal
464 cusps are present, but not well-developed (**Fig 5*e, f***).

465 **Distribution**

466 Between the Irrawaddy-Nmai Hka River and the Salween River in China and
467 Myanmar. The Dulongjiang valley, the upper tributary of the Nmai Hka River, may

serve as a dispersal barrier for hoolocks. Wild individuals are confirmed to occur on Mt. Gaoligong, and historical museum specimens are also known from further south at Gokteik, Shan State, northern Myanmar. Geissmann et al. [2013] estimated that a healthy population with ca. 50,000 individuals of eastern hoolock live in Shan State subtropical forests, and ca. 16,000 individuals live in montane rainforest in Kayah-Kayin (see below).

Comments

Although Groves [1967] suggested that the color of the hands and feet is lighter than the body color in *H. leuconedys*, we found no difference in coloration between the hands, feet, or bodies in examined individuals of either *H. leuconedys* or *H. tianxing*. The two specimens in our study sample from Gokteik, Shan State, Myanmar (USNM257988 and ZD.1933.7.29.15), which represents the southernmost record of *H. tianxing*, show minor morphological differences from individuals from Mt. Gaoligong; the male specimen is very similar to the holotype of *H. tianxing*, but the female possesses more white hair on the suborbital region than individuals from Mt. Gaoligong. Gokteik is 300 km southwest of Mt. Gaoligong, indicating that these observed differences may represent allopatric differentiation between hoolock populations in this region. However, more specimens from Shan, Kayah, and Kayin States need to be examined to assess whether this apparent variation is a genuine population-level characteristic.

Hoolocks no longer survive at the type locality of *H. tianxing*. The nearest well-

documented population occurs at Nankang (N24°49′, E98°46′, H: 1800-2300 m a.s.l.), 20 km away from Hongmushu in the southern part of Gaoligong National Nature Reserve. The vegetation in this region consists of humid montane evergreen broad-leaved forest dominated by species of Lauraceae, Fagaceae, Theaceae, and Magnoliaceae. Mean annual temperature in this region between October 2010 and September 2011 was 13.3°C; the lowest recorded mean monthly temperature was 6.4°C in January 2011, and the highest was 20.3°C in August 2010 [Fan et al., 2013]. Annual rainfall was 1801.4 mm during this period; rainfall was greater than 200 mm in each rainy season month from May to October, except in September 2011 (198.1 mm), and was less than 100 mm in each dry season month from November to April [Fan et al., 2013].

Discussion

Confidence of the molecular results

Genomic-scale hybridization capture has been demonstrated to constitute a valid and powerful approach to recover endogenous DNA for ancient and non-invasive sampling, and is extremely useful for conservation of threatened species [Perry et al., 2010]. In this study, our enrichments were able to recover whole mitogenomes efficiently for eight of the 11 fecal samples. One potential issue might be the involvement of so-called nuclear mitochondrial DNA sequences (NUMTs), which commonly exist in primates [Karanth, 2008]; the NUMTs, however, should be at low

enough levels to not influence base calling or subsequent assemblage accuracy [Li et al., 2012].

The relationships between Hylobatid genera are highly supported in our analyses (PP=1.0); but they are characterized by short internal branches (**Fig. 6**), a finding similar to previous studies [Kim et al., 2011; Springer et al., 2012; Thinh et al., 2010a]. This finding also matches the conclusions of the recent study using whole gibbon genome sequences by Carbone et al. [2014], who suggested a near-instantaneous diversification among the living Hylobatid genera.

According to our mitogenomic analyses, the MRCA of living gibbons lived around 6.79 Ma, which is slightly older than the estimate of 5 Ma based on nuclear genome data Carbone et al. [2014]. Our result is very similar to the gibbon MRCA age estimate given by Springer et al. [2012]. The timing of divergence between *H. hoolock* and taxa previously classified as *H. leuconedys* was around 1.14 Ma (1.38-0.93 Ma), overlapping with the estimates given in two previous studies (1.42 (1.90-0.97) in Thinh et al. [2010a]; 1.96 (4.4-0.22) in Springer et al. [2012]).

Support for the new taxon

Groves [1967] recognized *H. hoolock* and *H. leuconedys* based on characters shown by a series of skulls, as well as on four soft tissue characters, namely the color of the preputial tuft, the shape of the eyebrow streaks, the color of the suborbital hair, and the color of the chin hair. His taxonomic assessments were further confirmed by molecular phylogenetic analyses [Thinh et al., 2010a]. Here, we found that these

531 characters are equally prominent and distinguishable between *H. leuconedys* sensu
532 stricto and *H. tianxing.* Skull shape in hominoids is generally conserved while the shape
533 of postcanine teeth is usually variable [Uchida, 1996a]. Nevertheless, the 87-93%
534 correct assignments of individual specimens using each of the morphometric and GM
535 data in the DFAs support the occurrence of morphologial differentiation. Similarly, the
536 differatiation on the lower p4 is not clear-cut by itself. However, clear morphological
537 differentiation between populations is apparent when considering these characteristics
538 together.

539 Morphological discrimination is also congruent with divergence of the
540 mitochondrial genomes. We acknowledge that mitogenomic gene trees can differ from
541 nuclear genomic trees, as seen in primates for example in recent analysis of the "odd-
542 nosed" Asian colobines [Liedigk et al., 2012]. However, the two clades representing *H.*
543 *leuconedys* and *H. tianxing* are each strongly supported as monophyletic in our analysis,
544 and diverged in the middle Pleistocene (ca. 0.49 Ma), suggesting long-term matrilineal
545 isolation. In addition, the K2P distance between *H. leuconedys* and *H. tianxing* (1.2%)
546 is similar to the differentiation observed between other gibbon species, e.g., between
547 *Nomascus annamensis* and *N. gabriellae* (1.26%) and between *N. leucogenys* and *N.*
548 *siki* (1.0%) [Thinh et al., 2010c]. Similarly, the estimated divergence time between *H.*
549 *leuconedys* and *H. tianxing* is similar to or greater than estimated divergence times
550 between other primate species in Asia (Table 2). All of these taxa are recognized as full
551 species in the most recent taxonomic review of the world's primates [Mittermeier et al.,
552 2013].

553 Mt. Gaoligong, situated along the border of China and Myanmar, is a hotspot of
554 new species discovery, with recent discoveries including other species of primates
555 [Geissmann et al., 2011], as well as other vertebrates, e.g. amphibians [Yang et al.,
556 2016a, b]. This high discovery rate at least partly reflects the fact that these mountains
557 have been difficult to access in the past, so that few expeditions have been carried out,
558 and subsequently most animal groups have never been studied in detail. Most of these
559 new species are locally endemic; Mt. Gaoligong is the westernmost part of the
560 Hengduan Mountain Chain, which was formed during the uplift of the Himalayas
561 [Zhong & Ding, 1996], and is geographically isolated from the other mountains in
562 southwestern China by the Salween River valley. The "sky-island" topography and
563 associated unfavorable valley habitats are likely to have driven extensive physical
564 isolation, allopatric speciation, and high endemism in vertebrate populations [He &
565 Jiang, 2014]. Our discovery of *H. tianxing* provides further evidence of the unique local
566 fauna of Mt. Gaoligong, and it is very likely that new species are still to be described
567 in other taxonomic groups, many of which remain understudied and need to be re-
568 examined.

569 Groves [1967] and Choudhury [2013] noticed morphological differences in
570 hoolocks from the east and west of the Irrawaddy River. Groves [1967] also reported
571 that three of the 22 *H. leuconedys* specimens he examined did not show white chins,
572 and eight specimens did not have white hair under the eyes. However, he hesitated to
573 erect any further hoolock taxa because at the time "too few specimens of either sex are
574 available from the east of the Irrawaddy River to determine whether further splitting

575 may be required". Following our analysis of a further eight historical specimens and 14
576 wild animals from the east of the river, we support the suggestion that the Irrawaddy-
577 Nmai Hka River is likely to act as a barrier for different hoolock taxa, on the basis of
578 external and craniodental morphological differences and the divergence of
579 mitochondrial genomes.

580 **Individuals or specimens of particular significance**

581 Based on a studbook of captive hoolock gibbons compiled in 2011, we identified
582 a hybrid hoolock family in Kunming Zoo (Hehe♂ × Maomao♀). This pair reproduced
583 five times, and was the most successful captive breeding hoolock pair in any Chinese
584 zoo. Unfortunately, the adult pair and three of their five offspring (KNHMZ
585 2007090801, KNHMZ 2007082102, and another juvenile) died in 2007, possibly due
586 to a flu-like infection, although two male offspring (Dandan and Xiaobao) still survive.
587 The male had the typical white beard of *H. leuconedys* (YQL, personal observation),
588 but a photograph of the adult female shows the typical morphology of *H. tianxing*. Their
589 three male offspring (Xiaobao, Dandan, and KNHMZ 2007090801; Fig. S7a-b) all have
590 white hair on their chins and genital tufts, but do not have white hair under their eyes,
591 and their white beards are not as conspicuous as in typical *H. leuconedys* males (**Fig S2**
592 **h-j**). Genetic analysis of maternally inherited mitochondrial sequence data places them
593 in the *H. tianxing* clade (**Fig 7**). We conclude that these offspring are *H. leuconedys* ×
594 *H. tianxing* hybrids. Xiaobao is now paired with a morphologically typical *H.*
595 *leuconedys* female (Baimei) in Kunming Zoo; mitochondrial genetic analysis of the
596 offspring of this pair (Jiaojiao and Yuanyuan) places them as expected in the *H.*

leuconedys clade (**Fig 7**).

One skin specimen of an adult female (KIZ LS970114) was placed in the *H. leuconedys* clade in our phylogenetic analysis (**Fig 7**). Morphologically, this specimen resembles *H. leuconedys* in having thick white hair between its eyes (Fig. 7c); it was, however, reportedly collected from Tengchong County, Yunnan, which is within the geographic distribution of *H. tianxing*. Its original collection record contains no further information on either the collector, collection date, skull or body measurements. We consider it is highly possible that this specimen in fact originated in Myanmar, and was bought in Tengchong.

Conservation implications

The eastern hoolock, based on an assessment comprising populations of both *H. leuconedys* and *H. tianxing*, is currently listed as Vulnerable on the IUCN Red List [Brockelman & Geissmann, 2008], because a large population of 310,000-370,000 individuals (estimated based on very limited field surveys) has been reported from Myanmar [Geissmann et al., 2013]. As the hoolock population on the east bank of the Irrawaddy River represents a new species, its formal conservation status must also be re-evaluated. According to the most recent available survey data from 2008 and 2009, the total population size of *H. tianxing* in China is less than 200 individuals, and the population is highly fragmented across different forest areas [Fan et al., 2011]. Illegal hunting, habitat destruction, degradation and fragmentation, and the stochastic effects of small population size and isolation all threaten the future of *H. tianxing* in China

618 [Fan et al., 2011; Fan, 2016]. Based on average group density and area of suitable
619 habitat, Geissmann et al. [2013] estimated the total population of hoolocks in Kachin
620 State to be 240,000-290,000 individuals. This estimate is likely to include both *H.*
621 *tianxing* and *H. leuconedys*, although hoolocks have a limited distribution on the east
622 bank of the Nmai Hka River, suggesting that most of the Myanmar hoolocks in this
623 estimate are likely to be *H. leuconedys*. Three infant or small juvenile hoolocks have
624 been confiscated by the Chinese border police in the last two years, and one small
625 juvenile hoolock from Myanmar was raised as a pet by a woman in Dulongjiang,
626 Yunnan; all these individuals were *H. leuconedys*. The population of *H. tianxing* in
627 Kachin State is therefore likely to be very small if it even still survives. A larger
628 population of *H. tianxing* might still survive in the southern part of its proposed range;
629 Geissmann et al. [2013] estimated that approximately 50,000 hoolocks occur in the
630 subtropical forest of Shan State and 16,000 individuals occur in the montane rainforest
631 of Kayah and Kayin States. These populations are distributed on the east bank of the
632 Irrawaddy River, and therefore are likely to represent *H. tianxing*. These populations,
633 however, face a series of threats including hunting, illegal trade and rapid habitat loss
634 [Geissmann et al., 2013]. It is difficult to evaluate the conservation status of *H. tianxing*
635 without more robust information on the status of these poorly-known populations, but
636 we propose that *H. tianxing* should probably be assessed as Endangered on the IUCN
637 Red List, under criterion A4acd [IUCN, 2001].

638 Only 21 captive hoolock individuals are recorded in Chinese zoos in the hoolock
639 studbook [Yang, 2011]. We surveyed 22 captive hoolocks in China during this study,

most of which were, however, not listed in the studbook. We found that only two of these individuals can be assigned to *H. tianxing*. Although it is likely that other captive hoolocks that we did not survey may also be *H. tianxing* individuals, the total number of captive individuals of this species must be very small, and we know of no captive *H. tianxing* females in China.

Only two pairs of either eastern hoolock species are known to have bred in China before 2011: in Kunming Zoo and Beijing Zoo [Yang, 2011]. The pair in Kunming Zoo died in 2007, and the other pair and another adult female in Beijing Zoo died in 2005. Kunming Zoo currently has a new hoolock pair (Xiaobao♂ × Baimei♀), which has bred successfully three times, and another hoolock pair in Dehong Wildlife Rescue Center (DH3♂ × DH2♀) gave birth in 2015; as discussed above, however, Xiaobao is a *H. leuconedys* × *H. tianxing* hybrid, whereas Baimei, DH3 and DH2 are all *H. leuconedys* individuals. Further investigation of hoolocks currently held in Chinese captive facilities, together with accurate species identification of captive hoolock individuals, is necessary in order to establish a national conservation breeding program for *H. leuconedys*, and to evaluate whether a similar conservation breeding program is feasible for *H. tianxing.*

Acknowledgments

We are grateful to Nancy B. Simmons, Eileen Westwig and Brian O'Toole (American Museum of Natural History), Darren P. Lunde (National Museum of Natural

661 History, Smithsonian Institution), Hopi E. Hoekstra and Judy Chupasko (Museum of
662 Comparative Zoology, Harvard University), and Song Li (Kunming Institute of
663 Zoology) for access to or loan specimens under their care. We would like to thank
664 Jinshuo Zhang, Penglai Fan, Ran Dai and the late Alan Mootnick for help in collecting
665 fecal samples and/or checking specimens. This research was supported by a National
666 Natural Science Foundation of China grant (#31160424) to P.F.F., a China Green
667 Foundation grant to P.F.F., a National Program for Support of Top-notch Young
668 Professionals in China grant to P.F.F., and a Ministry of Science and Technology of
669 China grant (no. 2012FY110800) to W.Z.W. Except for historical museum specimens,
670 no gibbon was killed or captured during this research. All field research reported in this
671 manuscript was permitted by the Management Bureau of Gaoligongshan National
672 Nature Reserve, and adhered to the legal requirements of China and the American
673 Society of Primatologists' principles for the ethical treatment of nonhuman primates.

866 **Figure Legends.**

867 **Fig 1**. Field localities for eastern hoolocks, and collection localities for museum
868 specimens of eastern and western hoolocks. The distribution and type localities of *H.*
869 *hoolock hoolock* (red, Garo Hills), *H. h. mishmiensis* (gray, Delo), *H. leuconedys*
870 (yellow, Sumprabum) and *H. tianxing* (blue, Homushu) are shown.

871 **Fig 2**. Photos of male and female hoolocks from different taxa and geographic
872 populations. Photos of *H. h. hoolock* and *H. h. mishmiensis* are from Choudhury (2013).
873 **Fig 3.** A hoolock specimen from Homushu Pass, Mt. Gaoligong (AMNH M-43068,
874 upper) and the holotype of *H. leuconedys* (NHM ZD.1950.391, lower), showing (left to
875 right) eye brows and suborbital area, beard, and genital tuft.
876 **Fig 4.** PCA and DFA for hoolock taxa, using morphometric measurements (a-b), shape
877 of the outline of the upper M2 (c-d), and shape of the outline of the lower m2 (e-f).
878 **Fig 5.** Lower p4 of different hoolock species and geographic populations.
879 **Fig 6.** Bayesian tree of various catarrhines estimated using complete mitochondrial
880 genome sequence data. Branch lengths represent time. Node bars indicate the 95% CI
881 for the clade age. Unless specified, all interspecific relationships are strongly supported
882 (PP=1.0). PPs lower than 1.0 are shown in grey. Numbers above the nodes indicate
883 Bayesian posterior probabilities, numbers below the nodes refer to median ages.

884 **Fig 7**. Mitochondrial gene tree for hoolocks, showing two major clades within *Hoolock*
885 *leuconedys* sensu lato. Specimens shaded in grey were originally identified as *H.*
886 *hoolock*. Node numbers indicate Bayesian posterior probabilities. Branch lengths

represent substitutions/site.

Fig 7.

Table 1. Comparison of external characteristics between *Hoolock tianxing* and other hoolock taxa.

	H. leuconedys	*H. tianxing*	*H. h. hoolock*	*H. h. mishmiensis*
Ventral pelage in males	Brownish	Brownish	Black	Black
Gap between brow-streaks in males	Wide	Widest	Narrow	Narrow
Brow-streaks in males	Thick	Thin	Thick	Thickest
Genital tuft in males	White or silvery	Black or brown	Black or faintly grizzled	Black with buffy or rufescent buff
Beard on chin in males	Less prominent	Less prominent	Prominent	Prominent
	White or buffy	Black or brown	Black	Black
Gap between brow-streaks in females	Conspicuous	Conspicuous	Inconspicuous	Inconspicuous
Brow-streaks in females	Downturned	Downturned	Slightly concave	Horizontal
	More white between eyes	Less white between eyes		

Table 2. Estimated divergence times between gibbon and other Asian primate sister species based on mitochondrial data.
